Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: at LWW.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6 pm, EST.

Stephen E. Straus, 1946–2007

Steve Straus was the consummate physician–scientist with broad interests in the basic science and clinical aspects of viral and immunological diseases and therefore was an ideal person to serve as clinical virology editor for *Fields Virology*. We were fortunate to work with him in his role as associate editor for the third through fifth editions of *Fields Virology*. However, unfortunately, with Steve's premature death in 2007, we lost our friend, colleague, and fellow editor. Steve's medical training and accomplishments are detailed elsewhere (*J Infect Dis* 2007;196:963–964). His research interests were broad and included the molecular biology and pathogenesis of varicella-zoster and herpes simplex viruses, acyclovir suppression of oral and genital herpes simplex viruses, antiviral drug resistance, clinical testing of herpes simplex virus and varicella zoster virus vaccines, chronic active Epstein–Barr virus, chronic fatigue syndrome, and autoimmune lymphoproliferative syndrome. Steve was one of the leading scientists in the National Institutes of Health intramural program, serving as chief of the Laboratory of Clinical Investigation at the National Institute of Allergy and Infectious Diseases and the founding director of the National Center for Complementary and Alternative Medicine.

Steve cowrote the chapter on varicella zoster virus, and additionally worked effectively as an associate editor, for the third to fifth editions of *Fields Virology*. He seemed to read and edit the chapters immediately upon their submission, amazing us with his ability to do all of this on top of his other responsibilities. Steve was diagnosed with brain cancer in 2004 but insisted on editing chapters for the fifth edition right through the compiling of the chapters. The book was published in early 2007, not long before his death in May 2007.

On behalf of everyone who contributed to the sixth edition of *Fields Virology*, we dedicate this book to the memory of Stephen E. Straus, MD.

Carlos F. Arias, MD

In the early 1980s, Bernie Fields originated the idea of a virology reference textbook that combined the molecular aspects of viral replication with the medical features of viral infections. This broad view of virology reflected Bernie's own research, which applied molecular and genetic analyses to the study of viral pathogenesis, providing an important part of the foundation for the field of molecular pathogenesis. Bernie led the publication of the first three editions of *Virology* but unfortunately died soon after the third edition went into production. The third edition became *Fields Virology* in his memory, and it is fitting that the book continues to carry his name.

We are pleased that the printed book of the sixth edition of *Fields Virology* contains four-color art throughout and that an e-book version accompanies the printed book as well. We have increased the numbers of figures in each chapter, and with the color and availability of the figures from the e-book for use as slides, most chapters should have sufficient figures for slides for one lecture. There have been continued significant advances in virology since the previous edition 6 years ago, and all of the chapters have been updated to reflect these advances. Our increased knowledge of virology has caused us to use shortened lists of key references (up to 200 in most cases) in the printed book to save space, whereas complete reference lists appear as part of the e-book. We have retained the general organization of the earlier editions for the sixth edition of *Fields Virology*. Section I contains chapters on general aspects of virology, and Section II contains chapters on replication and medical aspects of specific virus families and specific viruses of medical importance. In Section I, we have added a new emphasis on virus discovery in the Diagnostic Virology chapter and emerging viruses in the Epidemiology chapter to address the interest in discovery of new viruses and emerging viruses. In Section II, we have added new chapters on circoviruses and mimiviruses and have added a new section on Chikungunya virus to the alphavirus chapter.

Numerous chapters have been updated to include the latest information on outbreaks during the past 5 years, including pandemic H1N1 influenza, new adenovirus serotypes, noroviruses, human polyomaviruses, the re-emergence of West Nile virus in North America, novel coronaviruses, novel Coxsackie and rhino viruses, and other emerging and re-emerging viruses. Important advances in antivirals, including new hepatitis C virus protease inhibitors and HIV integrase inhibitors, have been described. As with the previous edition, we have continued to combine the medical and replication chapters into a single chapter to eliminate duplication and to present a more coherent presentation of that specific virus or virus family. The main emphasis continues to be on viruses of medical importance and interest; however, other viruses are described in specific cases where more is known about their mechanisms of replication or pathogenesis. Although not formally viruses, prions are still included in this edition for historical reasons and because of the intense interest in the infectious spongiform encephalopathies.

We wish to thank Lisa Holik of Harvard Medical School, Richard Lampert of Lampert Consultancy, Grace Caputo of Dovetail Content Solutions, Chris Miller of Aptara, and Leanne Vandetty and Tom Gibbons and all of the editorial staff members of Lippincott Williams & Wilkins for all their important contributions to the preparation of this book.

VOLUME 1

SECTION I:

General Virology 1

- 1** Virology: From Contagium Fluidum to Virome 1
Lynn W. Enquist and Vincent R. Racaniello

- 2** Principles of Virology 21
Richard C. Condit

- 3** Principles of Virus Structure 52
Stephen C. Harrison

- 4** Virus Entry and Uncoating 87
Ari Helenius

- 5** Viral Replication Strategies 105
Sean Whelan

- 6** Virus Assembly 127
Eric Hunter

- 7** Viruses, Cell Transformation, and Cancer 153
Daniel DiMaio and Hung Fan

- 8** Innate Responses to Viral Infections 189
Akiko Iwasaki and Ruslan Medzhitov

- 9** Adaptive Immune Response to Viral Infections 214
Thomas J. Braciale, Young S. Hahn, and Dennis R. Burton

- 10** Pathogenesis of Viral Infection 254
Mark T. Heise and Herbert W. Virgin

- 11** Virus Evolution 286
Edward C. Holmes

- 12** Epidemiology 314
Neal Nathanson and William J. Moss

- 13** Antiviral Agents 338
Donald M. Coen and Douglas D. Richman

- 14** Immunization Against Viral Diseases 374
Barney S. Graham, James E. Crowe, Jr., and Julie E. Ledgerwood

- 15** Diagnostic Virology 414
Gregory A. Storch and David Wang

SECTION II:

Specific Virus Families 453

Picornaviridae

- 16** *Picornaviridae*: The Viruses and Their Replication 453
Vincent R. Racaniello

- 17** Enteroviruses: Polioviruses, Coxsackieviruses, Echoviruses, and Newer Enteroviruses 490
Mark A. Pallansch, M. Steven Oberste, and J. Lindsay Whitton

- 18** Rhinoviruses 531
James E. Gern and Ann C. Palmenberg

- 19** Hepatitis A Virus 550
F. Blaine Hollinger and Annette Martin

Calciviridae

- 20** *Calciviridae*: The Noroviruses 582
Kim Y. Green

Astroviridae

- 21** Astroviruses 609
Ernesto Méndez and Carlos F. Arias

Togaviridae

- 22** *Togaviridae* 629
Richard J. Kuhn

- 23** Alphaviruses 651
Diane E. Griffin

The Virome: How Many Viruses Are There? Where Are They? Why Are They There?

Pathogen Discovery

Arnold Levine's Afterword: d'Herelle's Dream and Koch's Postulates (see eBook)

Virology has had a remarkable history. Even though humans did not realize viruses existed until the late 1880s, viral diseases have shaped the history and evolution of life on the planet. As far as we know, all living organisms, when studied carefully, are infected by viruses. These smallest microbes exert significant forces on every living thing, including themselves. The consequences of viral infections have not only altered human history, they have powerful effects on the entire ecosystem. As a result, virologists have gone to extraordinary lengths to study, understand, and eradicate these agents. It is noteworthy that just as the initial discovery of viruses required new technology (porcelain filters), uncovering the amazing biology underlying viral infections has gone hand in hand with new technology developments. Indeed, virologists have elucidated new principles of life processes and have been leaders in promoting new directions in science. For example, many of the concepts and tools of molecular biology and cell biology have been derived from the study of viruses and their host cells. This chapter is an attempt to review selected portions of this history as it relates to the development of new concepts in virology.

THE CONCEPT OF VIRUSES AS INFECTIOUS AGENTS

A diverse microbial world of bacteria, fungi, and protozoa had been widely accepted by the last half of the 19th century. An early proponent of the germ theory of disease was the noted German anatomist Jacob Henle of Gottingen (the discoverer of Henle's loop and the grandfather of 20th-century virologist Werner Henle). He hypothesized in 1840 that specific diseases were caused by infectious agents that were too small to be observed with the light microscope. However, he had no evidence for such entities, and consequently his ideas were not generally accepted. It would take the work of Louis Pasteur and Henle's student, Robert Koch, before it became evident that microbes could cause diseases.

Three major advances in microbiology came together to set the stage for the development of the concept of a submicroscopic agent that would come to be called a virus (e-Table 1.1). The first advance concerned spontaneous generation of organisms, which for years had been both supported and refuted by a variety of experiments. Louis Pasteur (1822–1895) used his swan-neck flasks to strike a mortal blow to the concept of spontaneous generation. Afterward Pasteur went on to study fermentation by different microbial agents. From his work he concluded that “different kinds of microbes are associated with different kinds of fermentations,” and he soon extended this concept to diseases. Pasteur’s reasoning strongly influenced Robert Koch (1843–1910), a student of Jacob Henle and a country doctor in a small German village. Koch developed solid media to isolate colonies of bacteria to produce pure cultures, and stains to visualize the microorganisms. With these tools in hand, Koch identified the bacterium that causes anthrax (*Bacillus anthracis*, 1876) and tuberculosis (*Mycobacterium tuberculosis*, 1882). Joseph Lister (1827–1912), a professor of surgery in Glasgow, had heard about Pasteur’s work, and he surmised that a sterile field should be maintained during surgery. Although many other scientists of that day contributed tools and concepts, it was principally Pasteur, Lister, and Koch who put together a new experimental approach for medical science.

These observations led Robert Koch to formalize some of Jacob Henle’s original ideas for defining whether a microorganism is the causative agent of a disease. Koch’s postulates state that (a) the organism must be regularly found in the lesions of the disease, (b) the organism must be isolated in pure culture, (c) inoculation of such a pure culture of organisms into a host should initiate the disease, and (d) the organism must be recovered once again from the lesions of the host. By the end of the 19th century, these concepts outlined an experimental method that became the dominant paradigm of medical microbiology. It was only when these rules broke down and failed to yield a causative agent that the concept of a virus was born.

THE BIRTH OF VIROLOGY

Pathogen Discovery, 1886–1903 (e-Table 1.1)

Adolf Mayer (1843–1942) was a German agricultural chemist and director of the Agricultural Experiment Station at Wageningen in The Netherlands when he was asked to investigate a disease of tobacco. He named the affliction tobacco mosaic disease after the dark and light spots that appeared on infected leaves (e-Fig. 1.1). To investigate the nature of the disease, Mayer inoculated healthy plants with the juice extracted from diseased plants by grinding up the infected leaves in water. Mayer reported that, “in nine cases out of ten (of inoculated plants), one will be successful in making the healthy plant...heavily diseased”.¹³¹ Although these studies established the infectious nature of the tobacco mosaic disease, neither a bacterial agent nor a fungal agent could be consistently cultured or detected in these extracts, so Koch’s postulates could not be satisfied. In a preliminary communication in 1882,¹³⁰ Mayer speculated that the cause could be a “soluble, possibly enzyme-like contagium, although almost any analogy for such a supposition is failing in science.” Later Mayer concluded that the mosaic disease “is bacterial, but that the infectious forms have not yet been isolated, nor are their forms and mode of life known”.¹³¹

A few years later, Dimitri Ivanofsky (1864–1920), a Russian scientist working in St. Petersburg, was commissioned by the Russian Department of Agriculture to investigate the cause of a tobacco disease on plantations in Bessarabia, Ukraine, and the Crimea. Ivanofsky repeated Mayer’s observations by showing that the sap of infected plants contained an agent that could transmit the disease to healthy plants. But he added an important step—before the inoculation step, he passed the infected sap through a Chamberland filter (e-Fig. 1.2). This device, made of unglazed porcelain and perfected by Charles Chamberland, one of Pasteur’s collaborators, contained pores small enough to retard most bacteria. Ivanofsky reported to the Academy of Sciences of St. Petersburg on February 12, 1892, that “the sap of leaves infected with tobacco mosaic disease retains its infectious properties even after filtration through Chamberland filter candles”.⁹⁴

Ivanofsky, like Mayer before him, failed to culture an organism from the filtered sap and could not satisfy Koch’s postulates. Consequently he suggested that a toxin (not a living, reproducing substance) might pass through the filter and cause the disease. As late as 1903, when Ivanofsky published his thesis,⁹⁵ he still believed that he had been unable to culture the bacteria that caused this disease. Bound by the dogma of Koch’s postulates, Ivanofsky could not make a conceptual leap. It is therefore not surprising that Pasteur, who worked on the rabies vaccine¹⁴⁵ at the same time (1885), never investigated the unique nature of the infectious agent.

The conceptual leap was provided by Martinus Beijerinck (1851–1931), a Dutch soil microbiologist who collaborated with Adolf Mayer at Wageningen. Unaware of Ivanofsky’s work, in 1898 Beijerinck independently found that the sap of infected tobacco plants could retain its infectivity after passage through a Chamberland filter. But he also showed that the filtered sap could be diluted and regain its “strength” after replication in living, growing tissue of the plant. This observation showed that the agent could reproduce (therefore, it was not a toxin) but only in living tissue, not in the cell-free sap of the plant. Suddenly it became clear why others could not culture the pathogen outside its host. Beijerinck called this agent a *contagium vivum fluidum*,¹⁰ or a contagious living liquid. He sparked a 25-year debate about whether these novel agents were liquids or particles. This conflict was resolved when d’Herelle developed the plaque assay in 1917³⁶ and when the first electron micrographs were taken of tobacco mosaic virus (TMV) in 1939.¹⁰⁴

Mayer, Ivanofsky, and Beijerinck each contributed to the development of a new concept: a novel organism smaller than bacteria—an agent defined by the pore size of the Chamberland filter—that could not be seen in the light microscope, and could multiply only in living cells or tissue. The term *virus*, from the Latin for slimy liquid or poison,⁸⁹ was at that time used interchangeably for any infectious agent, and so the agent of tobacco mosaic disease was called tobacco mosaic virus, or TMV. The literature of the first decades of the 20th century often referred to these infectious entities as filterable agents, and this was indeed the operational definition of viruses. Sometime later, the term *virus* became restricted in use to those agents that fulfilled the criteria developed by Mayer, Ivanofsky, and Beijerinck, and that were the first agents to cause a disease that could not be proven by using Koch’s postulates.

Shortly after this pioneering work on TMV, the first filterable agent from animals was identified by Loeffler and Frosch—foot-and-mouth disease virus.¹²² The first human virus discovered was yellow fever virus (1901), by Walter Reed and his team in Cuba.¹⁵⁴

The years from 1930 to 1956 were replete with the discovery of a plethora of new viruses (e-Table 1.2). In fact, in this short time, virologists found most of the viruses we now know about. More fascinating perhaps is that these studies laid the groundwork for the birth of molecular virology.

Plant Viruses and the Chemical Period: 1929–1956

For the next 50 years, TMV played a central role in research that explored the nature and properties of viruses. With the development of techniques to purify proteins in the first decades of the 20th century came the appreciation that viruses were proteins and so could be purified in the same way. Working at the Boyce Thompson Institute in Philadelphia, Vinson and Petre (1927–1931) precipitated infectious TMV—using an infectivity assay developed by Holmes⁸⁸—from the crude sap of infected plants using selected salts, acetone, or ethyl alcohol.¹⁹³ They showed that the infectious virus could move in an electric field, just as proteins did. At the same time, H. A. Purdy-Beale, also at the Boyce Thompson Institute, produced antibodies in rabbits that were directed against TMV and could neutralize the infectivity of this agent.¹⁵¹ This observation was taken as further proof of the protein nature of viruses, although it was later realized that antibodies recognize chemicals other than proteins. With the advent of purification procedures for viruses, both physical and chemical measurements of the virus became possible. The strong flow birefringence of purified preparations of TMV was interpreted (correctly) to show an asymmetric particle or rod-shaped particle.¹⁸⁰ Max Schlesinger,¹⁶⁷ working on purified preparations of bacteriophages in Frankfurt, Germany, showed that the virions were composed of proteins and contained phosphorus and ribonucleic acid. This observation led to the first suggestion that viruses were composed of nucleoproteins. The crystallization of TMV in 1935 by Wendell Stanley,¹⁷³ working at the Rockefeller Institute branch in Princeton, New Jersey, brought this infectious agent into the world of the chemists. Within a year, Bawden and Pirie^{8,9} had demonstrated that crystals of TMV contained 0.5% phosphorus and 5% RNA. The first “view” of a virus came from x-ray crystallography using these crystals to show rods of a constant diameter aligned in hexagonal arrays containing RNA and protein.¹⁶ The first electron micrographs of any virus were of TMV, and they confirmed that the virus particle is shaped like a rod¹⁰⁵ (e-Fig. 1.3).

The x-ray diffraction patterns¹⁶ suggested that TMV was built from repeating subunits. These data and other considerations led Crick and Watson³³ to realize that most simple viruses had to consist of one or a few species of identical protein subunits. By 1954–1955, techniques had been developed to dissociate TMV protein subunits, allowing reconstitution of infectious TMV from its RNA and protein subunits⁶⁴ and leading to an understanding of the principles of virus self-assembly.²⁵

The concept that viruses contained genetic information emerged as early as 1926, when H. H. McKinney reported the isolation of “variants” of TMV with a different plaque

morphology that bred true and could be isolated from several geographic locations.^{132,133} Seven years later, Jensen confirmed McKinney’s observations¹⁰¹ and showed that the plaque morphology phenotype could revert. Avery’s DNA transformation experiments with pneumococcus⁵ and the Hershey-Chase experiment with bacteriophages,⁸³ both demonstrated that DNA was genetic material. TMV had been shown to contain RNA, not DNA, and this nucleic acid was shown to be infectious, and therefore comprise the genetic material of the virus, in 1956^{64,72}—the first demonstration that RNA could be a genetic material. Studies on the nucleotide sequence of TMV RNA confirmed codon assignments for the genetic code, added clear evidence for the universality of the genetic code, and helped to elucidate the mechanisms of mutation by diverse agents.⁶³ Research on TMV and related plant viruses has contributed significantly to both the origins of virology and its development as a science.

BACTERIOPHAGES

Early Years: 1915–1940

Frederick W. Twort was superintendent of the Brown Institution in London when he discovered viruses of bacteria in 1915. In his research, Twort was searching for variants of vaccinia virus (the smallpox vaccine virus), which would replicate in simple defined media outside living cells. In one of his experiments, he inoculated nutrient agar with an aliquot of the smallpox vaccine. The virus failed to replicate, but bacterial contaminants flourished on the agar medium. Twort noticed that some of these bacterial colonies changed visibly with time and became “watery looking” (i.e., more transparent). The bacteria within these colonies were apparently dead, as they could no longer form new colonies on fresh agar plates. He called this phenomenon glassy transformation. Simply adding the glassy transforming principle could rapidly kill a colony of bacteria. It readily passed through a porcelain filter, could be diluted a million-fold, and when placed upon fresh bacteria would regain its strength, or titer.^{188–190}

Twort published these observations in a short note¹⁹⁰ in which he suggested that a virus of bacteria could explain glassy transformation. He then went off to serve in World War I, and when he returned to London, he did not continue this research.

While Twort was puzzled by glassy transformation, Felix d’Herelle, a Canadian medical bacteriologist, was working at the Pasteur Institute in Paris. When a *Shigella* dysentery infection devastated a cavalry squadron of French soldiers just outside of Paris in August 1915, d’Herelle readily isolated and cultured the dysentery bacillus from filtered fecal emulsions. The bacteria multiplied and covered the surface of his agar plates, but occasionally d’Herelle observed clear circular spots devoid of growth. He called these areas *taches vierges*, or plaques. He followed the course of an infection in a single patient, noting when the bacteria were most plentiful and when the plaques appeared.^{35,36} Plaques appeared on the fourth day after infection and killed the bacteria in the culture dish, after which the patient’s condition began to improve.

d’Herelle found that a filterable agent, which he called a bacteriophage, was killing the *Shigella* bacillus. In the ensuing years he developed fundamental techniques in virology that are utilized to this day, such as the use of limiting dilutions to

determine the virus titer by plaque assay. He reasoned that the appearance of plaques showed that the virus was particulate, or “corpuscular,” and not a liquid as Beijerinck had insisted. d’Herelle also found that if virus was mixed with a host cell and then subjected to centrifugation, the virus was no longer present in the supernatant fluid. He interpreted this to mean that the first step of a virus infection is attachment, or adsorption, of virus to the host cell. Furthermore, viral attachment occurred only when bacteria sensitive to the virus were used, demonstrating that host specificity can be conferred at a very early step in infection. Lysis of cells and the release of infectious virus were also described in startlingly modern terms. d’Herelle clearly established many of the principles of modern virology.^{34,35}

Although d’Herelle’s bacteriophages lysed their host cells, by 1921 it had become apparent that under certain situations the virus and cell existed peacefully—a condition called lysogeny. In some experiments it became impossible to separate the virus from its host. This conundrum led Jules Bordet of the Pasteur Institute in Brussels to suggest that the transmissible agent described by d’Herelle was nothing more than a bacterial enzyme that stimulates its own production.²² Although incorrect, the hypothesis has remarkable similarities to modern ideas about prion structure and replication (see Chapter 77).

During the 1920s and 1930s, d’Herelle sought ways to use bacteriophages for medical applications, but he never succeeded. Furthermore, the basic research of the era was frequently dominated by the interpretations of scientists with the strongest personalities. Although it was clear that there were many diverse bacteriophages, and that some were lytic while some were lysogenic, their interrelationships remained ill defined. The highlight of this period was the demonstration by Max Schlesinger that purified phages had a maximum linear dimension of 0.1 micron and a mass of about 4×10^{-16} grams, and that they were composed of protein and DNA in roughly equal proportions.^{166,167} In 1936, no one quite knew what to make of that observation, but over the next 20 years it would begin to make a great deal of sense.

Phages and the Birth of Molecular Biology: 1938–1970 (e-Table 1.3)

Max Delbrück was trained as a physicist at the University of Göttingen, and his first position was at the Kaiser Wilhelm Institute for Chemistry in Berlin. There he joined a diverse group of individuals who were actively discussing how quantum physics related to an understanding of heredity. Delbrück’s interest in this area led him to develop a quantum mechanical model of the gene, and in 1937 he moved to the biology division at the California Institute of Technology to study genetics of *Drosophila*. Once there, he became interested in bacteria and their viruses, and teamed up with another research fellow, Emory Ellis,⁵¹ who was working with the T-even group of bacteriophages, T2, T4, and T6. Delbrück soon appreciated that these viruses were ideal for the study of virus replication, because they allowed analysis of how genetic information could determine the structure and function of an organism. Bacteriophages were also viewed as model systems for understanding cancer viruses or even for understanding how a sperm fertilizes an egg and a new organism develops. Together with Ellis, Delbrück showed that viruses reproduced in one step, in contrast to the multiplication of other organisms by binary

fission.⁵² This conclusion was drawn from the elegant one-step growth curve experiment, in which an infected bacterium liberates hundreds of phages synchronously after a half-hour period during which viral infectivity was lost (e-Fig. 1.4). The one-step growth curve became the experimental paradigm of the phage group.

When World War II erupted, Delbrück remained in the United States (at Vanderbilt University) and met an Italian refugee, Salvador E. Luria, who had fled to America and was working at Columbia University in New York (on bacteriophages T1 and T2). After their encounter at a meeting in Philadelphia on December 28, 1940, they went to Luria’s laboratory at Columbia where they spent 48 hours doing experiments with bacteriophages. These two scientists eventually established the “phage group,” a community of researchers focused on using bacterial viruses as a model for understanding life processes. Luria and Delbrück were invited to spend the summer of 1941 at Cold Spring Harbor Laboratory, where they pursued research on phages. The result was that a German physicist and an Italian geneticist joined forces during the war years to travel throughout the United States and recruit a new generation of biologists (e-Fig. 1.5).

When Tom Anderson, an electron microscopist at the RCA Laboratories in Princeton, New Jersey, met Delbrück, the result was the first clear pictures of bacteriophages.¹²⁶ At the same time, the first phage mutants were isolated and characterized.¹²⁵ By 1946, the first phage course was being taught at Cold Spring Harbor, and in March 1947, the first phage meeting attracted eight people. From these humble beginnings grew the field of molecular biology, which focused on the bacterial host and its viruses.

Developing the Modern Concept of Virology (see e-Tables 1.3 to 1.5)

The next 25 years (1950–1975) was an intensely productive period of bacteriophage research. Hundreds of virologists produced thousands of publications that covered three major areas: (a) lytic infection of *Escherichia coli* with the T-even phages; (b) the nature of lysogeny, using lambda phage; and (c) the replication and properties of several unique phages such as ϕ X174 (single-stranded circular DNA), the RNA phages, and T7. This work set the foundations for modern molecular virology and biology.

The idea of examining, at the biochemical level, the events occurring in phage-infected cells during the latent period had come into its own by 1947–1948. Impetus for this work came from Seymour Cohen, who had trained first with Erwin Chargaff at Columbia University, studying lipids and nucleic acids, and then with Wendell Stanley working on TMV RNA. His research direction was established when after taking Delbrück’s 1946 phage course at Cold Spring Harbor, Cohen examined the effects of phage infection on DNA and RNA levels in infected cells using a colorimetric analysis. The results showed a dramatic alteration of macromolecular synthesis in infected cells. This included cessation of RNA accumulation, which later formed the basis for detecting a rapidly turning-over species of RNA and the first demonstration of messenger RNA (mRNA).⁴ DNA synthesis also halted, but for 7 minutes, followed by resumption at a 5- to 10-fold increased rate. At the same time, Monod and Wollman showed that the synthesis of a cellular enzyme, the inducible β -galactosidase, was inhibited

after phage infection.¹³⁴ Based on these observations, the viral eclipse period was divided into an early phase, prior to DNA synthesis, and a late phase. More importantly, these results demonstrated that a virus could redirect cellular macromolecular synthetic processes in infected cells.³²

By the end of 1952, two experiments had a critical effect on virology. First, Hershey and Chase asked whether viral genetic information is DNA or protein. They differentially labeled viral proteins ($^{35}\text{SO}_4$) and nucleic acids ($^{32}\text{PO}_4$), and allowed the “tagged” particles to attach to bacteria. When they sheared the viral protein coats from the bacteria using a Waring blender, only DNA was associated with the infected cells.⁸³ This result proved that DNA had all the information needed to reproduce new virus particles. A year later, the structure of DNA was elucidated by Watson and Crick, a discovery that permitted full appreciation of the Hershey-Chase experiment.¹⁹⁵ The results of these two experiments formed a cornerstone of the molecular biology revolution.²⁶

While these blockbuster experiments were being carried out, G. R. Wyatt and S. S. Cohen were quietly making another seminal finding.²⁰⁷ They identified a new base, hydroxymethylcytosine, in the DNA of T-even phages, which replaced cytosine. This began a 10-year study of how deoxyribonucleotides were synthesized in bacteria and phage-infected cells, and it led to the critical observation that the virus introduces genetic information for a new enzyme into the infected cell.⁶⁰ By 1964, Mathews and colleagues had proved that hydroxymethylase does not exist in uninfected cells and must be encoded by the virus.³² These experiments introduced the concept of early enzymes, utilized in deoxypyrimidine biosynthesis and DNA replication,¹⁰⁹ and provided biochemical proof that viruses encode new information that is expressed as proteins in an infected cell. At the same time, phage genetics became extremely sophisticated, allowing mapping of the genes encoding these viral proteins. Perhaps the best example of genetic fine structure was done by Seymour Benzer, who carried out a genetic analysis of the rII A and B cistrons of T-even phages with a resolution of a single nucleotide (without doing any DNA sequencing!).¹³ Studies on viral DNA synthesis, using phage mutants and cell extracts to complement and purify enzyme activities *in vitro*, contributed a great deal to our understanding of DNA replication.¹ A detailed genetic analysis of phage assembly, utilizing the complementation of phage assembly mutants *in vitro*, revealed how complex structures are built by living organisms using the principles of self-assembly.⁴⁷ The genetic and biochemical analysis of phage lysozyme helped to elucidate the molecular nature of mutations,¹⁷⁶ and the isolation of phage amber mutations (nonsense mutations) provided a clear way to study second-site suppressor mutations at the molecular level.¹⁴ The circular genetic map of the T-even phages¹⁷⁶ was explained by the circularly permuted, terminally redundant (giving rise to phage heterozygotes) conformation of these DNAs.¹⁸⁶

The remarkable reprogramming of viral and cellular protein synthesis in phage-infected cells was dramatically revealed by an early use of sodium dodecyl sulfate (SDS)–polyacrylamide gels,¹¹² showing that viral proteins are made in a specific sequence of events. The underlying mechanism of this temporal regulation led to the discovery of sigma factors modifying RNA polymerase and conferring gene specificity.⁷⁵ The study of gene regulation at almost every level (transcription, RNA

stability, protein synthesis, protein processing) was revealed from a set of original contributions derived from an analysis of phage infections.

Although this remarkable progress had begun with the lytic phages, no one knew quite what to make of the lysogenic phages. This situation changed in 1949 when André Lwoff began his studies with *Bacillus megaterium* and its lysogenic phages at the Pasteur Institute. By using a micromanipulator, Lwoff could show that single lysogenic bacteria divided up to 19 times without liberating a virus particle. No virions were detected when lysogenic bacteria were broken open by the investigator. But from time to time a lysogenic bacterium spontaneously lysed and produced many viruses.¹²⁸ Ultraviolet light was found to induce the release of these viruses, a key observation that began to outline this curious relationship between a virus and its host.¹²⁹ By 1954, Jacob and Wollman^{97,98} at the Pasteur Institute had made the important observation that a genetic cross between a lysogenic bacterial strain and a non-lysogenic recipient resulted in the induction of the virus after conjugation, a process they called zygotic induction. In fact, the position of the lysogenic phage or prophage in the chromosome of its host *E. coli* could be mapped by interrupting mating between two strains.⁹⁸ This experiment was crucial for our understanding of lysogenic viruses, because it showed that a virus behaved like a bacterial gene on a chromosome in a bacterium. It was also one of the first experimental results to suggest that the viral genetic material was kept quiescent in bacteria by negative regulation, which was lost as the chromosome passed from the lysogenic donor bacteria to the nonlysogenic recipient host. This conclusion helped Jacob and Monod to realize as early as 1954 that the “induction of enzyme synthesis and of phage development are the expression of one and the same phenomenon”.¹²⁸ These experiments laid the foundation for the operon model and the nature of coordinate gene regulation.

Although the structure of DNA was elucidated in 1953¹⁹⁵ and zygotic induction was described in 1954, the relationship between the bacterial chromosome and the viral chromosome in lysogeny was still referred to as the attachment site and literally thought of in those terms. The close relationship between a virus and its host was appreciated only when Campbell proposed the model for lambda integration of DNA into the bacterial chromosome,²⁷ based on the fact that the sequence of phage markers was different in the integrated state than in the replicative or vegetative state. This model led to the isolation of the negative regulator or repressor of lambda, a clear understanding of immunity in lysogens, and one of the early examples of how genes are regulated coordinately.¹⁵⁰ The genetic analysis of the lambda bacteriophage life cycle is one of the great intellectual adventures in microbial genetics.⁸² It deserves to be reviewed in detail by all students of molecular virology and biology.

The lysogenic phages such as P22 of *Salmonella typhimurium* provided the first example of generalized transduction,²¹⁰ whereas lambda provided the first example of specialized transduction.¹³⁷ The finding that viruses could not only carry within them cellular genes, but transfer those genes from one cell to another, provided not only a method for fine genetic mapping but also a new concept in virology. As the genetic elements of bacteria were studied in more detail, it became clear that there was a remarkable continuum from lysogenic phages to episomes,

transposons and retrotransposons, insertion elements, retroviruses, hepadnaviruses, viroids, and prions. Genetic information moves between viruses and their hosts to the point where definitions and classifications begin to blur. The genetic and biochemical concepts that emerged from the study of bacteriophages made the next phase of virology possible. The lessons of the lytic and lysogenic phages were often relearned and modified as the animal viruses were studied.

ANIMAL VIRUSES

Cell Culture Technology and Discovery: 1898–1965 (see e-Tables 1.1 to 1.3)

Once the concept of viruses as filterable agents took hold, many diseased animal tissues were subjected to filtration to determine if a virus were involved. Filterable agents were found that were invisible in a light microscope, and replicated only in living animal tissue. There were some surprises, such as the transmission of yellow fever virus by a mosquito vector,¹⁵⁴ specific visible pathologic inclusion bodies (virions and subviral particles) in infected tissue,^{95,142} and even viral agents that can “cause cancer”.^{50,159}

Throughout this early time period (1900–1930), a wide variety of viruses were found (see e-Tables 1.1 and 1.2) and characterized with regard to their size (using the different pore sizes of filters), resistance to chemical or physical agents (e.g., alcohol, ether), and pathogenic effects. Based on these properties alone, it became clear that viruses were a very diverse group of agents. Some were even observable in the light microscope (vaccinia in dark-field optics). Some were inactivated by ether, whereas others were not. Viruses were identified that affected every tissue type. They could cause chronic or acute disease; they were persistent agents or recurred in a periodic fashion. Some viruses caused cellular destruction or induced cellular proliferation. For the early virologists, unable to see their agents in a light microscope and often confused by this great diversity, their studies certainly required an element of faith. In 1912, S. B. Wolbach, an American pathologist, remarked, “It is quite possible that when our knowledge of filterable viruses is more complete, our conception of living matter will change considerably, and that we shall cease to attempt to classify the filterable viruses as animal or plant”.²⁰⁴

The way out of this early confusion was led by the plant virologists and the development of techniques to purify viruses and characterize both the chemical and physical properties of these agents (see previous section, The Plant Viruses and the Chemical Period: 1929–1956). The second path out of this problem came from the studies with bacteriophages, where single cells infected with viruses in culture were much more amenable to experimental manipulation than were virus infections of whole animals. Whereas the plant virologists of that day were tethered to their greenhouses, and the animal virologists were bound to their animal facilities, the viruses of bacteria were studied in Petri dishes and test tubes. Nevertheless, progress was made in the study of animal viruses one step at a time: from studying animals in the wild, to laboratory animals, such as the mouse⁶⁶ or the embryonated chicken eggs,²⁰⁵ to the culture of tissue, and then to single cells in culture. Between 1948 and 1955, a critical transition converting animal virology into a laboratory science came in four important steps: Sanford and colleagues

at the National Institutes of Health (NIH) overcame the difficulty of culturing single cells¹⁶³; George Gey at Johns Hopkins Medical School cultured and passaged human cells for the first time and developed a line of immortal cells (HeLa) from a cervical carcinoma⁷¹; and Harry Eagle at the NIH developed an optimal medium for the culture of single cells.⁴⁶ In a demonstration of the utility of all these advances, Enders and his colleagues showed that poliovirus could replicate in a nonneuronal human explant of embryonic tissues.⁵⁴

These ideas, technical achievements, and experimental advances had two immediate effects on the field virology. They led to the development of the polio vaccine, the first ever produced in cell culture. From 1798 to 1949, all the vaccines in use (smallpox, rabies, yellow fever, influenza) had been grown in animals or embryonated chicken eggs. Poliovirus was grown in monkey kidney cells that were propagated in flasks.^{84,117} The exploitation of cell culture for the study of viruses began the modern era of molecular virology. The first plaque assay for an animal virus in culture was done with poliovirus,⁴³ and it led to an analysis of poliovirus every bit as detailed and important as the contemporary work with bacteriophages. The simplest way to document this statement is for the reader to compare the first edition of *General Virology* by S. E. Luria in 1953¹²⁴ to the second edition by Luria and J. E. Darnell in 1967,¹²⁷ and to examine the experimental descriptions of poliovirus infection of cells. The modern era of virology had arrived, and it would continue to be full of surprises.

The Molecular and Cell Biology Era of Virology (see e-Tables 1.4 to 1.6)

The history of virology has so far been presented chronologically or according to separate virus groups (plant viruses, bacteriophages, animal viruses), which reflects the historical separation of these fields. In this section, the format changes as the motivation for studying viruses began to change. Virologists began to use viruses to probe questions central to understanding all life processes. Because viruses replicate in and are dependent on their host cells, they must use the rules, signals, and regulatory pathways of the host. By using viruses to probe cells, virologists began to make contributions to all facets of biology. This approach began with the phage group and was continued by the animal virologists. The recombinant DNA revolution also took place during this period (1970 to the present), and both bacteriophages and animal viruses played a critical and central role in this revolution. For these reasons, the organization of this section focuses on the advances in cellular and molecular biology made possible by experiments with viruses. Some of the landmarks in virology since 1970 are listed in e-Tables 1.4 to 1.6.

The Role of Animal Viruses in Understanding Eukaryotic Gene Regulation

The closed circular and superhelical nature of polyomavirus DNA was first elucidated by Dulbecco and Vogt⁴² and Weil and Vinograd.¹⁹⁷ This unusual DNA structure was intimately related to the structure of the genome packaged in virions of simian vacuolating virus 40 (SV40). The viral DNA is wound around nucleosomes⁷⁰; when the histones are removed, a superhelix is produced. The structure of polyoma viral DNA served as an excellent model for the *E. coli* genome²⁰⁶ and the mammalian

chromosome.¹¹³ Viral genomes have unique configurations not found in other organisms, such as single-stranded DNA (ssDNA),¹⁷¹ plus or minus strand RNA, or double-stranded RNA (dsRNA) as modes of information storage.

Many elements of the eukaryotic transcription machinery have been elucidated with viruses. The first transcriptional enhancer element (acts in an orientation- and distance-independent fashion) was described in the SV40 genome,⁷⁶ as was a distance- and orientation-dependent promoter element observed with the same virus. The transcription factors that bind to the promoter, SP-1,⁴⁴ or to the enhancer element, such as AP-1 and AP-2,¹¹⁶ and which are essential to promote transcription along with the basal factors, were first described with SV40. AP-1 is composed of fos and jun family member proteins, demonstrating the role of transcription factors as oncogenes.²¹ Indeed, the great majority of experimental data obtained for basal and accessory transcription factors come from *in vitro* transcription systems using the adenovirus major late promoter or the SV40 early enhancer–promoter.¹⁹⁶ Our present-day understanding of RNA polymerase III promoter recognition comes, in part, from an analysis of the adenovirus VA gene transcribed by this polymerase.⁶²

Almost everything we know about the steps of messenger RNA (mRNA) processing began with observations made with viruses. RNA splicing of new transcripts was first described in adenovirus-infected cells.^{15,31} Polyadenylation of mRNA was first observed with poxviruses,¹⁰² the first viruses shown to have a DNA-dependent RNA polymerase in the virion.¹⁰³ The signal for polyadenylation in the mRNA was identified using SV40.⁵⁹ The methylated cap structure found at the 5′ end of most mRNAs was first discovered on reovirus mRNAs.⁶⁷ What little is known about the process of RNA transport out of the nucleus has shown a remarkable discrimination of viral and cellular mRNAs by the adenovirus E1B-55 Kd protein.¹⁴⁷

Most of our understanding of translational regulation has come from studies of virus infected cells. Recruitment of ribosomes to mRNAs was shown to be directed by the 5′ cap structure first discovered on reovirus mRNAs. The nature of the protein complex that allows ribosomes to bind the 5′ cap was elucidated in poliovirus-infected cells, because viral infection leads to cleavage of one of the components, eIF4G. Internal initiation of translation was discovered in cells infected with picornaviruses (poliovirus and encephalomyocarditis virus).^{99,146} Interferon, discovered as a set of proteins that inhibits viral replication, was subsequently found to induce the synthesis of many antiviral gene products that act on translational regulatory events.^{92,93} Similarly, the viral defenses against interferon by the adenovirus VA RNA has provided unique insight into the role of eIF-2 phosphorylation events.¹⁰⁸ Mechanisms for producing more than one protein from a eukaryotic mRNA (there is no “one mRNA one protein” rule in bacteria) were discovered in virus-infected cells, including polyprotein synthesis, ribosomal frameshifting, and leaky scanning. Posttranslational processing of proteins by proteases, carbohydrate addition to proteins in the Golgi apparatus, phosphorylation by a wide variety of important cellular protein kinases, or the addition of fatty acids to membrane-associated proteins have all been profitably studied using viruses. Indeed, a good deal of our present-day knowledge of how protein trafficking occurs and is regulated in cells comes from the use of virus-infected cell

systems. The field of gene regulation has derived many of its central tenets from the study of viruses.

Animal Viruses and the Recombinant DNA Revolution

The discovery of the enzyme reverse transcriptase,^{6,185} not only elucidated the replication cycle of retroviruses, but also provided an essential tool to convert RNA molecules to DNA, which could then be cloned and manipulated. The first restriction enzyme map of a chromosome was done with SV40 DNA, using the restriction enzymes HindII plus HindIII DNA,^{37,38} and the first demonstration of restriction enzyme specificity was carried out with the same viral DNA cleaved with EcoRI.^{136,138} Some of the earliest DNA cloning experiments involved insertion of SV40 DNA into lambda DNA, or human β -hemoglobin genes into SV40 DNA, yielding the first mammalian expression vectors.⁹⁶ A debate about whether these very experiments were potentially dangerous led to a temporary moratorium on all such recombinant experiments following the scientist-organized Asilomar Conference. From the earliest experiments in the field of recombinant DNA, several animal viruses had been developed into expression vectors to carry foreign genes, including SV40,⁷⁴ the retroviruses,¹⁹⁸ the adenoviruses,^{69,78} and adeno-associated virus.¹⁶² which has the remarkable property of preferential integration into a specific genomic site.¹¹⁰ Modern-day strategies of gene therapy rely on some of these recombinant viruses. Hemoglobin mRNA was first cloned using lambda vectors, and the elusive hepatitis virus C (non-A, non-B) viral genome was cloned from serum using recombinant DNA techniques, reverse transcriptase, and lambda phage vectors.³⁰

Animal Viruses and Oncology

Much of our present understanding of the origins of human cancers is a consequence of work on two major groups of animal viruses: retroviruses and DNA tumor viruses. Oncogenes were first discovered in the genome of Rous sarcoma virus, and subsequently shown to exist in the host cell genome.¹⁷⁴ Since those seminal studies, virologists have identified a wide variety of oncogenes that have been captured by retroviruses (see Chapter 8). Additional oncogenes were identified when they were activated by insertion of the proviral DNA of retroviruses into the genomes of cells.⁷⁷ The second group of genes that contribute to the origins of human cancers, the tumor suppressor genes,¹¹⁸ has been shown to be intimately associated with the DNA tumor viruses. Genetic alterations at the p53 locus are the single most common mutations known to occur in human cancers—they are found in 50% to 80% of all cancers.¹¹⁹ The p53 protein was first discovered in association with the SV40 large T-antigen.^{115,120} SV40, the human adenoviruses, and the human papillomaviruses all encode oncoproteins that interact with and inactivate the functions of two tumor suppressor gene products, the retinoblastoma susceptibility gene product (Rb) and p53.^{40,44,115,120,164,200,201} Our understanding of the roles of cellular oncogenes and the tumor suppressor genes in human cancers would be far less significant without the insight provided by studies with these viruses. Curiously, none of the four human polyoma viruses central to these studies was associated with human cancers. However, in 2008, a new polyomavirus associated with Merkel cell carcinoma was discovered.⁵⁷

Viruses that cause cancers have provided some of the most extraordinary episodes in modern animal virology.¹³⁵ The recognition of a new disease and the unique geographic distribution of Burkitt's lymphoma in Africa²⁰ set off a search for viral agents that cause cancers in humans. From D. Burkitt²⁴ to Epstein, Achong, and Barr⁵⁶ to W. Henle and G. Henle,⁸¹ the story of the Epstein-Barr virus and its role in several cancers, as well as in infectious mononucleosis, is a science detective story without rival. Similarly, the identification of a new pathologic disease, adult T-cell leukemia, in Japan by K. Takatsuki^{181,191} led to the isolation of a virus that causes the disease by I. Miyoshi and Y. Hinuma²⁰⁸ and the realization that this virus (human T-cell leukemia virus type 1 [HTLV-1]) had been identified previously by Gallo and his colleagues.¹⁴⁹ Even with the virus in hand, there is still no satisfactory explanation of how this virus contributes to adult T-cell leukemia.

An equally interesting detective story concerns hepatitis B virus and hepatocellular carcinoma. By 1967, S. Krugman and his colleagues¹¹¹ had strong evidence indicating the existence of distinct hepatitis A and B viruses, and in the same year B. Blumberg²⁰ had identified the Australia antigen. Through a tortuous path, it eventually became clear that the Australia antigen was a diagnostic marker—the coat protein—for hepatitis B virus. Although this discovery freed the blood supply of this dangerous virus, Hilleman at Merck Sharp & Dohme and the Chiron Corporation (which later isolated the hepatitis C virus) went on to produce the first human vaccine that prevents hepatitis B infections and very likely hepatocellular carcinomas associated with chronic virus infections (see Chapter 69). The idea of a vaccine that can prevent cancer—first proven with the Marek's disease virus and T-cell lymphomas in chickens,^{18,49}—comes some 82 to 85 years after the first discoveries of tumor viruses by Ellerman, Bang, and Rous. An experiment is under way in Taiwan, where 63,500 newborn infants have been inoculated to prevent hepatitis B infections. Based on the epidemiologic predictions, this vaccination program should result in 8,300 fewer cases of liver cancer in that population in 35 to 45 years.

Vaccines and Antivirals

Among the most remarkable achievements of our century is the complete eradication of smallpox, a disease with a greater than 2,000-year-old history.⁷⁹ In 1966, the World Health Organization began a program to immunize all individuals who had come into contact with an infected person. This strategy was adopted because it simply was not possible to immunize entire populations. In October 1977, Ali Maolin of Somalia was the last person in the world to have a naturally occurring case of smallpox (barring laboratory accidents). Because smallpox has no animal reservoir and requires person-to-person contact for its spread, most scientists agree that we are free of this disease, at least as a natural infection.⁷⁹ As a consequence, most populations have not maintained immunity to the virus and the world's populations are becoming susceptible to infection. Many governments now fear the use of smallpox virus as a weapon of bioterrorism, and the debate continues over whether to destroy the two known stocks of smallpox virus in the United States and Russia.⁸⁰ As a consequence, the development of new, more effective vaccines and safe anti-smallpox virus drugs has risen high on the list of priorities for some countries, and such vaccines have already been stockpiled in

the United States. It is paradoxical that humankind's most triumphant medical accomplishment is now tarnished by the spectre of biowarfare.

The Salk and Sabin poliovirus vaccines were the first products to benefit from the cell culture revolution. In the early 1950s in the United States, just before the introduction of the Salk vaccine, about 21,000 cases of poliomyelitis were reported annually. Today, thanks to aggressive immunization programs, polio has been eradicated from the United States (see Chapters 18 and 19).¹⁴¹ As of this writing, only three countries have seen interruption of wild-type poliovirus circulation: Nigeria, Afghanistan, and Pakistan. With the substantial financial support of the Gates Foundation, there is hope that global immunization campaigns can lead to eradication of poliomyelitis from the planet.

The first viral vaccines deployed included infectious vaccines, attenuated vaccines, inactivated virus vaccines, and subunit vaccines. Both the Salk inactivated virus vaccine and the recombinant hepatitis B virus subunit vaccine were products of the modern era of virology. Today many new vaccine technologies are either in use or are being tested for future deployment.^{3,23,168} These include recombinant subunit vaccines, virus-like particle vaccines, viral antigens delivered in viral vectors comprising vaccinia virus or adenovirus, and DNA plasmids that express viral proteins from strong promoters. Therapeutic vaccines boost the immune system using specific cytokines or hormones in combination with new adjuvants to stimulate immunity at specific locations in the host or to tailor the production of immune effector cells and antibodies. Considering that the first vaccines for smallpox were reported in the Chinese literature of the 10th century,⁵⁸ vaccinology has clearly been practiced well before the beginning of the field of virology.

Although vaccines have been extraordinarily successful in preventing specific diseases, up until the 1960s, few natural products or chemotherapeutic agents that cured or reduced viral infections were known. That situation changed dramatically with the development of Symmetrel (amantadine) by Dupont in the 1960s as a specific influenza A virus drug. Soon after, acyclovir, an inhibitor of herpesviruses, was developed by Burroughs-Wellcome. Acyclovir achieves its remarkable specificity because to be active, it must be phosphorylated by the viral enzyme thymidine kinase before it can be incorporated into viral DNA by the viral DNA polymerase. This drug blocks herpes simplex virus type 2 (HSV-2) replication after reactivation from latency and stopped a growing epidemic in the 1970s and 1980s (Chapter 14). The development of other nucleoside analogs has led to many compounds effective against DNA viruses. Until the human immunodeficiency virus (HIV) epidemic, few drugs effective against RNA viruses other than the influenza A virus were known. As natural products, the interferons (Chapter 9) are used successfully in the clinic for hepatitis B and C infections, cancer therapy, and multiple sclerosis. The interferons, novel cytokines found in the course of studying virus interference,^{23,92,93} modulate the immune response and continue to play an increasing role in the treatment of many clinical syndromes.

Virology and the Birth of Immunology

Edward Jenner was a British surgeon who is credited with making the first smallpox vaccine in 1796, and has also been called

the “father of immunology.” Jenner began a long tradition of virology providing seminal discoveries about the immune response. Two examples will serve to illustrate this pattern.

Alick Issacs and Jean Lindenmann, while working at the National Institute for Medical Research in London, found that addition of heat-inactivated influenza virus to the chorioallantoic membrane of chicken eggs interfered with the replication of influenza virus. When they published this observation in 1957, they coined the term *interferon* (IFN).⁹² In the 1970s the protein was purified from cells by Sidney Pestka and Alan Waldman,¹⁶¹ and subsequently the genes encoding the proteins were cloned.⁷³ This allowed formal proof that IFN—by that time known to comprise a variety of different proteins—could interfere with viral replication. Extensive work with viruses showed that IFNs bind to cell-surface receptors, and through the JAK-STAT signal transduction pathway, induce the synthesis of more than 1,000 mRNAs that establish an antiviral state.³⁹ IFNs protect against both viral and bacterial infections, and also play a role in tumor clearance.

While working at the John Curtin School of Medical Research in Australia, Rolf Zinkernagel and Peter Doherty provided seminal insight into how cytotoxic T cells (CTLs) recognize virus-infected cells. They were studying infection of mice with lymphocytic choriomeningitis virus (LCMV). Because this virus is noncytopathic, they hypothesized that brain damage in infected mice was a consequence of CTLs attacking virus-infected cells. They made the observation that CTLs isolated from LCMV-infected mice lysed virus-infected target cells *in vitro* only if both cell types had the same major histocompatibility complex (MHC) haplotype. This requirement was termed MHC restriction.²¹¹ In other words, a CTL must recognize two components on a virus-infected cell: one virus specific and one from the host. Subsequent research revealed that CTLs recognize a short viral peptide bound to MHC class I (MHC-I) proteins on the surface of target cells. These observations revolutionized our understanding of T-cell-mediated killing, thereby establishing a foundation for understanding the general mechanisms used by the immune system to recognize both foreign microorganisms and self-molecules. The results have had wide implications for clinical medicine, not only in infection but also in areas such as cancer and autoimmune reactions in inflammatory diseases.

Emerging Viruses

In general, emerging viruses cause human infections that have not been seen or reported before. They usually attract the public's attention, often by media sound bites like “killer viruses emerge from the jungle.” The fact is that spread of infections through different hosts is well known in virology. Most so-called emerging infections represent zoonotic infections: infection of humans by a virus that normally exists in an animal population in nature.¹⁸⁷

Perhaps the most infamous emerging virus infection of the 20th century is the human immunodeficiency virus type 1, HIV-1, a retrovirus.⁸⁵ Progenitor HIV viruses exist in primates, and we now believe they infected humans as a result of hunting and slaughter for food.¹⁷⁰ HIV was first recognized as a new disease entity by clinicians and epidemiologists in the early 1980s, and they rapidly tracked down the venereal mode of virus transmission. The virus was detected in blood products

and transplant tissue. The immune system of HIV-infected individuals is severely compromised, which results in a variety of infections by usually benign microbes. The first published report of acquired immunodeficiency syndrome (AIDS) was in June 1981. Possible causative agents were first suggested in 1983,⁷ and then 1984.⁶⁸ Had this pandemic occurred in 1961 instead of 1981, neither the nature of retroviruses nor the existence of its host cell (CD4 helper T cell) would have been understood. HIV is a lentivirus (*lenti* is Latin for slow) and despite its recent appearance in humans, lentiviruses have been around for a long time. In fact, one of the first animal viruses to be identified in 1904 was the lentivirus that causes infectious equine anemia.

Many other examples of emerging viruses have attracted global concern and an exceptional rapid response of scientists and health officials.¹⁸⁷ The severe acute respiratory syndrome (SARS) and West Nile virus epidemics revealed the presence of a new human coronavirus (SARS), identified with unprecedented speed, and the invasion of an Old World virus into the Western hemisphere (West Nile virus).^{90,140} In 2006, chikungunya virus (an endemic virus infection in Africa) spread explosively to several countries where it was hitherto unknown.¹⁶⁹ On La Reunion Island, more than 40% of the population of 800,000 people was infected. The first appearance of avian influenza A (H5N1) virus in humans in 1997 produced fears of a pandemic of serious proportions because humans had no immunological history of infection by this avian strain.¹⁸² Soon thereafter, the emergence of the pandemic H1N1 influenza virus in 2009 produced similar worries because of the relationship of the virus to the deadly 1918 influenza epidemic.¹⁸⁴ The mobilization of world health networks, public health officials, vaccine producers, veterinarians, clinicians, and molecular virologists marked a new chapter in dealing with emerging diseases.

Epidemiology of Viral Infections

The study of the incidence, distribution, and control of disease in a population is an integral part of virology. The technology advancements of the last 50 years have provided epidemiology with a terrific boost. The discovery of specific molecular reagents (e.g., recombinant DNA technology, antibodies, polymerase chain reaction [PCR], rapid diagnostic tests, high volume DNA and RNA sequencing) now enables detection of virions, proteins, and nucleic acids in body fluids, tissue samples, or in the environment. Moreover, we now can compare and classify viral isolates rapidly, determine the relationships between virus strains, and track the spread of infections around the world. The marriage of behavioral, geographic, and molecular epidemiology made this a most powerful science.⁸⁷

The understanding of epidemics and pandemics of our most common viral infections such as influenza requires the perspectives of ecology, population biology, and molecular biology.^{106,182} G. Hirst and his colleagues (1941–1950) developed the diagnostic tools that permitted both the typing of the hemagglutinin (HA protein) of influenza A strains and the monitoring of the antibody response to this antigen in patients (see Chapters 42 and 43). These observations have been expanded, with more and more sophisticated molecular approaches, to prove the existence of animal reservoirs for influenza viruses, the reassortment of viral genome segments between human and

animal virus strains (antigenic shift), and a high rate of mutation (antigenic drift) caused by RNA-dependent RNA synthesis with no known RNA editing or corrective mechanisms.^{153,184} These molecular events that lead to episodic local epidemics and worldwide pandemics are understood in broad outline. Many viruses are now known to evolve at high rates following basic Darwinian principles in a time frame shorter than that of any other organism. Indeed, we now understand that RNA virus populations exist as a quasispecies or a swarm of individual viral genomes where every member is unique. Influenza viruses are successful because they have evolved to carry the very engines of evolution: mechanisms of mutation and recombination (reassortment). Influenza A virus has not been eliminated even with effective vaccines and antiviral drugs. Variants always arise that escape effective immune responses thorough high mutation (drift), and when co-infection occurs with viruses spreading from nonhuman hosts, new reassortants regularly arise. Expression of these new combinations of viral genes can change the pattern of infection from local to pandemic via an antigenic shift of its HA and NA subunit proteins. These studies (Chapters 42 and 43) have revealed an extraordinary lifestyle that reverberates around the planet in birds, farm animals, and humans. The study of the mechanisms of viral pathogenesis and modulation of the immune system have led to new insights in the virus–host relationship.

New technology discovered and developed over the last 35 years is changing the way viral infections are studied in the laboratory and in the field, and is changing our appreciation of epidemiology and virus ecology.¹⁸³ Amplification technologies such as PCR permit rapid sampling of viral nucleic acids without growth in culture or plaque purification. Microarray technology where discriminatory DNA sequences from all sequenced viral genomes are put on a single array enables rapid classification of PCR-amplified nucleic acids.¹⁹⁴ Rapid genome sequencing has revealed hitherto described viral genomes, relationships among viruses, and sequence heterogeneity within a virus population.¹²³ Mutations can be detected rapidly, documented, and localized in the viral genome. Importantly, the biological consequences can be monitored quickly. For example, in the late 1970s, viral epidemiologists were confronted with a highly transmissible, lethal infection of puppies.¹⁴⁴ In record time, scientists found that just two mutations in the capsid gene of feline parvovirus altered the host range such that the mutant could infect dogs. In less than a year, a completely new, highly pathogenic virus called canine parvovirus spread all around the world. Its evolution has continued to be monitored, and a highly effective vaccine was developed. A similar type of molecular archeology enabled scientists to analyze serum samples collected from patients in the 1950s in efforts to understand the origins of HIV.⁸⁵ Sequence analysis of the HIV genome from one sample (ZR 1959) suggested that the virus may have emerged in the 1940s to 1950s. Field studies in Africa of viruses present in primate feces indicated that HIV most likely derived from a chimpanzee lentivirus in Africa.¹⁷⁰ After the initial human infection, rapid mutation and selection established the first human variants of this lentivirus that replicated and continued to evolve as they spread through their new human hosts.

The advances in our understanding of the viral etiology of tumors pay tribute to the modern epidemiology strategy by D. Burkitt and K. Takatsuki, leading to the identification of Epstein-

Barr virus (EBV) and HTLV-1. Similarly, the recombinant DNA revolution overcame the problems of propagating human papillomaviruses. The human papillomaviruses (see Chapter 56) differ in transmission, location on the body, their nature of pathogenesis, and persistence. New technology permitted the identification of new virus serotypes, triggering epidemiologic correlations for high- or low-risk cancer viruses.²¹² The same technology enabled the development and use of an effective vaccine against cervical cancer. We cannot forget the considerable impact of veterinary virus epidemiology on our understanding of complicated human diseases. For example, careful epidemiologic work by Sigurdsson and colleagues on unusual diseases of sheep¹⁷⁵ provided the first understanding of slow infections in sheep (Visna-Maedi virus; a lentivirus) and infectious proteins (prions), which cause spongiform encephalopathies (Chapter 78).

As we describe in the next section, molecular epidemiology is reaching new levels of sophistication, not only in detecting new viruses, but also taking inventory of the viral ecosystem. Whether the next human epidemic will result from a novel variant of Ebola virus, coronavirus, or Norwalk virus, or the more likely possibility of a new pandemic variant of influenza virus, remains to be seen. The new technologies also enable analysis of virus populations in natural communities of nonhuman animals. For example, we can now monitor pandemic spread of avian influenza virus in wild birds and other nonhuman hosts.¹⁵³ These alternative hosts have never been sampled for virus populations in such molecular detail. New insights into the selection pressures and bottlenecks are emerging almost faster than the viruses. What is abundantly clear, however, is that the demographics of the human population on earth are changing at unprecedented rates (Table 1.1). Even as birth rates slow, our planet will house 8 to 10 billion people by 2050 to 2100. For the first time, there will be three to four times more people older than the age of 60 than younger than 3 to 4 years of age. Not only are we an aging population, we are moving to urban environments, with more than 20 to 30 cities containing more than 10 million people. Clearly, patterns of human behavior (increased population density, increased travel, increased ages of the population) will provide the environment for the selection of emerging viruses and the challenges to the new field of molecular epidemiology.

HOST–VIRUS INTERACTIONS AND VIRAL PATHOGENESIS

The technologies that contributed most to the modern era of virology (1960 to present), were advances in cell culture and molecular biology.⁵⁵ Virologists were able to describe the replicative cycles of viruses in great detail under well-defined conditions, and they demonstrated the elaborate interactions between viral genomes, viral proteins, and the cellular machinery of the host. As indicated previously, these advances resulted in an extraordinary inquiry into the functions of infected or uninfected host cells using the tools of both molecular biology and cell biology. As this approach matured, it became more reductionist in nature, and the questions became more detailed. However, some virologists used the new knowledge to move back to more complicated *in vivo* systems to study previously difficult problems in host–virus

TABLE 1.1 Advances and Challenges

Vaccines	<p>Yellow fever virus vaccine, live attenuated</p> <p>Salk and Sabin vaccines for poliovirus, killed and live attenuated</p> <p>Recombinant hepatitis B vaccine, subunit</p> <p>Vaccinia virus vaccine to eradicate natural smallpox virus from the planet</p> <p>Influenza virus vaccines, inactivated and live attenuated</p> <p>Varicella-zoster virus vaccines, live attenuated</p> <p>Rotavirus vaccines, live attenuated</p> <p>Measles vaccines, live attenuated</p> <p>Recombinant human papillomavirus vaccine, subunit; prevents cancers and virus infections</p>
Antiviral drugs	<p>Acyclovir against herpes simplex type 1 and type 2</p> <p>Combination therapy: Protease, reverse transcriptase, and integrase inhibitors against HIV</p> <p>Interferon therapy for hepatitis B and C</p> <p>Amantadine against influenza A virus</p> <p>Neuraminidase inhibitors against influenza virus</p>
Epidemiologic advances	<p>Understanding the molecular basis of antigenic shift and drift in influenza viruses</p> <p>Identification of the causes of AIDS and SARS</p> <p>Prion diseases recognized and mechanisms elucidated</p> <p>Deep sequencing, genome analysis; pathogen discovery, uncovering the molecular nature of epidemic and pandemic infections</p> <p>Recognition of the role of zoonotic infections in the emergence of new viral diseases</p> <p>Recognition of specific viruses as causative agents in human cancers</p> <p>Elucidation of the concept of viral quasispecies and the molecular biology of viral populations</p>
Viral pathogenesis	<p>Identification of viral virulence genes</p> <p>Identification of host genes affecting virus replication and spread</p> <p>Identification of the molecular bases for antiviral immune defenses (adaptive immunity)</p> <p>Identification of the molecular basis of front-line cellular defenses (intrinsic and innate immunity) including apoptosis and induction of defensive cytokines</p> <p>Understanding of the molecular basis for viral tropism</p> <p>Elucidation of the mechanisms involved in viral quiescence and persistence</p>
The challenges (societal)	<p>Population explosion: more people now live on the planet than at any time in our existence (predicted to be 8 to 10 billion in the next few decades)</p> <p>Population concentration: world populations are concentrating in large urban centers of 10 to 20 million people or more</p>
The challenges (scientific)	<p>Population demographics: for the first time there are more people older than the age of 60 than younger than the age of 4</p> <p>Population interactions: world populations interact physically at rates and extents never before possible</p> <p>Pandemic viral diseases and bioterrorism provide continuing challenges for human survival</p> <p>Research costs money: how do we alleviate the pressures on funding and support of fundamental research</p> <p>Discoveries cannot be predicted: how to balance true discovery research with applied (translational) research</p> <p>Public support: how do we develop support and advocacy for virology research</p> <p>Policy makers need to understand virology: more engagement of scientists with lawmakers and the general public</p> <p>Public education about vaccination and other public health issues</p> <p>Discovering an effective vaccine against HIV</p> <p>Developing vaccines against persistent viruses</p> <p>Discovering and developing new antiviral drugs</p> <p>Development of rapid viral diagnostic and identification strategies</p> <p>Coupling new technology with established procedures</p> <p>Balancing risks and benefits of dangerous pathogen research</p> <p>Developing surrogates for Koch's postulates in modern pathogen discovery programs</p> <p>Defining and understanding the composition and interplay of microbial communities inside and outside hosts (natural versus unnatural flora)</p>

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; SARS, severe acute respiratory syndrome.

interactions involving the natural host or animal models of infection. Chief among these new questions was, how does a virus cause disease processes in the animal? How do we quantify viral virulence and what is the genetic basis of an attenuated virus? These studies have identified, in selected viruses, a set of genes and functions that broadly influence our understanding of pathogenesis.

Despite an abundance of data, we have distilled six general categories relating to viral pathogenesis. Four of these involve viral gene products and two involve the hosts.

1. Mutations in genes that impair virus replication in the host, lower the threshold of pathogenesis by reducing the number of progeny produced. These mutations are found in essential genes (essential for life) *in vivo*.
2. A second class of mutations impairs virulence (reduces the degree of pathogenicity), but does not alter normal virus replication (at least in some cell or tissue types). Here, host- or tissue-range mutations are most common. Mutations can change the pattern of virion adsorption to a particular cell type and so prevent viral entry into a cell. Mutations in viral enhancer elements can alter viral transcription in selected cell types. In some viral genomes, mutations affect rates of translation such that virulence is reduced. A classic example comes from analysis of the attenuated strains of poliovirus in the Sabin vaccine. All three strains of the Sabin poliovirus vaccine contain mutations in the 5' untranslated region of the viral RNA genome, which impair translation of these RNAs, and as a consequence virus yields are reduced. As a result, after infection, viral replication occurs, the host is immunized, but disease does not occur.
3. A third class of genes affecting virulence is involved in producing products that modify the host defenses. Intrinsic host defenses depend on receptors inside and on the surface of cells that detect viral gene products. When these receptors are activated, cytokines can be produced to alert more global innate immune defenses, the cell may die by apoptosis, or autophagy may be induced to engulf virus particles. It is likely that every successful virus can bypass or modulate these most fundamental cell-autonomous defenses. Mutations in these primary defense systems or viral proteins that block them affect virulence and spread. Some viruses encode genes that produce viral homologs of host cytokines (virokines). These proteins are secreted from infected cells and modify the immune response to infection. Other viruses encode decoy receptors that bind host-produced cytokines and reroute the immune response as a result. Many viral genomes encode genes whose products block infected cells from undergoing apoptosis in response to a virus infection. Some viruses, such as African swine fever virus, secrete a pro-apoptotic factor that kills lymphocytes and enhances its virulence. Many viruses produce proteins that alter the MHC proteins (MHC-I and MHC-II; also known as human leukocyte antigens or HLA proteins). These complex proteins display on the cell surface, short peptides derived from newly made or newly ingested proteins inside the cell. T cells detect these complexes and respond if non-self-peptides are detected. Many viral infections alter the expression or function of these MHC proteins. Other viruses encode superantigens that stimulate or eliminate lymphoid cells of a selected specificity or with a class of receptors. HIV infection kills CD4 T cells and disrupts the immune response.
4. A fourth class of viral virulence genes enhances the spread of a virus in the host. Some viruses are released from infected cells at the apical or basolateral surface, permitting selected spread *in vivo*. Some RNA viruses acquire infectivity (maturation) only after specific proteolytic cleavage of their structural proteins. In some cases, maturation is accomplished by a viral protease and in others by a cellular protease, each with a specific amino acid sequence required for proper cleavage and resulting spread of the virus. Altering this sequence will affect virulence and overall transmissibility of the infection in a host population.
5. A fifth class involves host gene products. A wide variety of polymorphisms or mutations in the host result in modulated resistance or virulence of a virus. These host mutations can even be selected during viral epidemics, changing the gene pool of the surviving host population. In humans, polymorphisms in a chemokine receptor gene (a co-receptor) impart resistance to HIV infection at the level of viral absorption. New antiviral drugs have been designed to target this viral-cytokine interaction. Variations in the immune responses of diverse hosts in a population will result in large variations in viral virulence. The host mechanisms that minimize viral diseases after infection are certainly major topics in viral pathogenesis.
6. The final class involves the society and interaction of hosts. Changes in population density, lifestyles, cultural traditions, and economic factors all play a major role in viral virulence. Poliovirus was a minor endemic virus infection for 3,000 years before the introduction of improved sanitation in the last century. As a result, human populations were infected for the first time at a later age and large poliovirus epidemics resulted. It may not have been a coincidence that the worst influenza epidemic in the century, killing 20 to 40 million people, started in about 1918 toward the end of World War I, with so many people dislocated and moving about the world in very crowded and poor conditions. If there is a general lesson from history it is that cultural and environmental changes will surely play a role in the virulence of viruses in the future.

THE FUTURE OF VIROLOGY? (E-TABLE 1.7 AND TABLE 1.1)

The future of virology is unpredictable, but it is guaranteed to be exciting. Who knows what discoveries remain? Certainly, the number of astounding and groundbreaking discoveries in biology over the last 50 years is remarkable.⁵⁵ Most could not have been predicted or even imagined, prior to their discovery. That virologists participated in making many of these discoveries is no accident: Viral gene products have evolved to engage all the key nodes of biology ranging from the atomic to the organismal. We only have to be smart enough to figure out how to identify these nodes. The forces that will drive our field are technology development, public health, information processing, and, of course, personal curiosity. Indeed new life science technologies invariably

will give rise to new, unexpected insights in virology to meet our current challenges. That has been, and continues to be, the future of virology (see Table 1.1).

Despite a cloudy crystal ball, three general trends are likely to rise to the forefront of virology research over the next 10 years.

1. **The detailed understanding of the systems biology inherent in virus–host interactions.** Although virus particles are inanimate, it is the living, infected cell that delivers the phenotype promoted by the viral genome. The change of state of a cell or tissue from uninfected to infected is fertile ground for modern systems biology. The constellation of new gene products (viral and host) and altered host pathways produced in an infected cell give rise to biological outputs that go far beyond the single cell in the laboratory. Viruses offer useful modalities for the systems biologist. One can synchronize an infection and go from the uninfected to infected state within minutes, or use the same virus to produce an acute or a quiescent infection. Regulatory circuits, modulation of host defenses, emergence of pathogenesis, and modes of efficient transmission in a hostile environment, are all inherent in the nanobiology of viruses. How can a viral genome with so few genes relative to the host, dominate a cell and the host so quickly and dynamically? How does it all work? How has evolution produced such diversity of infected cell phenotypes? Microarrays, PCR, mass spectroscopy, microfluidics, large-scale nucleic-acid sequencing, massive database assembly, and computer modeling are what toothpicks and Petri dishes were to the students of the Delbrück phage school 60 years ago.
2. **The understanding of viruses as integral participants in the ecosystem.** Such knowledge means uncovering the multiple interrelationships and interactions of all viruses and their hosts. This is ecology, but on a scale that has hitherto been unimaginable for virologists. Viruses exist wherever life is found, and they are the most abundant entities on the planet. Indeed their biomass rivals that of the prokaryotes. Estimates are that we know less than 1% of the viral genomes on the planet, but first principles inform us that there can be only a limited number of genome strategies for replication and expression of information. Therefore, despite what appears to be incredible diversity, we will be able to identify new viruses by the unique signatures of a viral genome. The viral ecology problem, therefore, is one of knowing what is out there and why. The powerful techniques of interrogating virus populations in the wild for their RNA, DNA, proteins, and unique small molecules have changed the worldview of ecologists and molecular biologists alike. The new biology will require the intellectual firepower of computer scientists, engineers, chemists, and physicists, as well as biologists. As part of this growing knowledge of the viral ecosystem, virologists will come to be more ecumenical in their studies and not balkanize the field into animal and plant virology or viruses of single cell hosts.
3. **Health of humans and the world.** The fundamental need for public health measures is unprecedented, as the human population is now greater than ever before. However, despite all attempts to prove otherwise, humans are not the

top of the food chain. Every living thing ultimately engages every other entity directly or indirectly—and, as far as we know, every living thing is infected with viruses. These infections shape human existence on the planet. A human centric view of public health is short-sighted. First principles tell us that all successful viruses today carry a collection of genes that have survived the best defenses that hosts can muster. Our knowledge of the microbial world must be used to inform our national and international health policies. The bedrock of old-fashioned public health policies cannot be ignored: clean water, sewage treatment, proper nutrition, and management of epidemic childhood disease by vaccines. However, the continuing divide between rich and poor nations, the conflicts among ethnic and religious groups, the changing climate, and resulting calamities of drought and other natural disasters stress even these most basic attempts at maintaining public health. Certainly the high-tech approach to public health of developed counties will find no purchase in those countries where the basics of survival are lacking.

Intrinsic and Extrinsic Defenses Against Viral Infections

It is likely that considerable work in the future will be directed to the host defenses that meet viral infections in the first minutes to hours. All viral infections begin as individual, single-cell events that either are resolved or expand to produce the characteristic phenotypes of the persistent or acute infection. Ancient single-cell pathways of response to external stimuli have been honed over millions of years to provide cells and communities of cells, a repertoire of defensive actions that are now being revealed. Every cell is capable of responding to infection immediately (so-called intrinsic resistance) by processes whose nature and actions will fuel discovery research in the near future.^{17,61} These processes act immediately upon infection, before the so-called innate and adaptive immune responses are called into action. We understand some of these processes, such as apoptosis in some detail, but others, including RNA interference (RNAi), autophagy, DNA repression, and the restriction factors first defined by retrovirologists, remain fertile ground for discovery.^{28,29,41} The interaction between signals of early warning from single cells with the local multicellular innate immune response and the global adaptive immune response are likely to be key to recognizing and responding to the various patterns of viral infections that arise in nature. Primary questions concerning the molecular biology and cellular biology of persistent and latent infection cannot be answered without knowledge of early defense responses of single cells and local tissues.

DNA microarray technology has enabled the measurement of the whole genome responses of single cells exposed to a wide variety of viral infections.¹⁰⁰ The systematic profiling of gene-expression changes has provided an exceptionally rich database from which we now are learning of cell-common and cell-specific responses to infection. The differences and similarities are proving to be the proverbial gold mine of information on the definition of evolutionarily conserved host-defense components and viral gene products that counter them. Understanding the relationship of common cell-stress responses and

pathogen-specific responses and counter-responses will certainly provide insights into potential diagnostic and therapeutic targets for viral infections.¹⁰⁰

Viruses and Cancer

Since the 1960s, seven different human viruses have been isolated, identified, and shown to be associated with the etiology of human cancer.¹³⁵ Surprisingly, even after 50 years, we have only a rudimentary understanding of the oncogenic pathogenesis of these infectious agents.¹³⁵ The first cancer-associated virus was discovered in 1964 when Epstein, Achong, and Barr⁵⁶ detected herpesvirus particles in cells obtained from a Burkitt's lymphoma.²⁴ The DNA episomes of the Epstein-Barr virus (or EBV) have been consistently found to be associated with some types of B-cell lymphomas. Despite this 40-year period, it remains unclear how or even if this virus actually causes this lymphoma. Although it is certain that the EBV genome contains one or more oncogenes (latent membrane protein 1, LMP-1), they are not expressed in the lymphoma cells. The only viral gene product expressed in these lymphoma cells is Epstein-Barr nuclear antigen 1 (EBNA-1), and its possible role of contributing to lymphomas is still controversial. Similarly the HTLV-1 viral genome does not contain a cellular oncogene, and it does not integrate into the host-cell DNA near a cellular proto-oncogene in a consistent fashion. Therefore, HTLV-1 does not employ the two most common mechanisms for tumor formation observed with the retroviruses. There is no clear association of any hepatitis B or C gene products in the causation of liver cancers. Rather it appears that immune destruction of liver cells followed by the regeneration of this tissue activates several growth factors made by the surrounding tissue resulting in fibrosis. The local milieu of inflammation and the positive feedback loop for growth drives the division of liver cells and hepatocellular carcinoma. This complex mix of infection, immune-mediated cell death, and chronic inflammation in a tissue with regenerative capacity is challenging to analyze. Although Kaposi's sarcoma herpesvirus also encodes potential oncogenes, no clear mechanism of how it initiates or propagates cancer is available. On the other hand, studies of the human papillomaviruses⁴⁵ have provided a mechanistic understanding of how these viruses transform cells. The viral E7 protein binds to the cellular retinoblastoma protein and inactivates its function, thereby initiating entry of the cell into the cell cycle and division. The viral E6 protein binds the cellular p53 protein and promotes its ubiquitylation and proteolytic degradation, thereby preventing cellular apoptosis.¹⁶⁵ More research is needed to fully understand the mechanisms that lead to cancers after infection by these viruses.¹⁹⁹

A Role for Systems Biology in Virology

Not too long ago, molecular virology was limited to studies of one virus and one gene or gene product at a time. More complex studies often were seen as "descriptive." Times have changed! New technology enables virologists to interrogate simultaneously many viruses and large groups of genes or gene products in ever-expanding environments and biological networks. In this context, a network is defined as the interconnected intracellular processes that control everything within a cell, for example, DNA replication, processes of gene expression, organelle bio-

genesis, and metabolism to name a few.¹³⁹ The definition also encompasses networks of intercellular communication at the tissue, organ, and whole-organism level. Virologists are beginning to embrace a tenet of systems biology where information flows through these networks and disease arises when these networks are perturbed. Viral gene products cause changes in network architecture and thereby alter the dynamics of information flow. Future studies of viral pathogenesis are likely to involve identification and understanding of specific viral signatures of network imbalance that do not affect just one pathway but alter the fundamental homeostatic balance.^{19,55,152,179}

Genomics and the Predictive Power of Sequence Analysis

The development of technologic advances in biology often drives new approaches and permits one to ask novel questions that could not even be framed in the past. In the last decade of the 20th century, rapid and inexpensive DNA-sequencing methods paved the way to sequence the genomes of many viruses and their hosts. This created large databases containing information about the variation of DNA or RNA sequences within a single virus (e.g., HIV, influenza) and permitted predictions about the nature of the mutations that were driving selective changes, mutation frequencies of different viruses, and evolutionary changes from isolates around the world. The correlations of these sequence variations with drug resistance, changes in the genetic background of the host, and virulence have been informative. By combining this information with the three-dimensional structure of the influenza A hemagglutinin (HA) protein, J. Plotkin and colleagues have examined codon use in this gene and suggested that the degeneracy of codon use was being optimized to permit changes in amino acids at critical positions in this protein, so as to reduce the impact of the immune response to this virus.¹⁴⁸ Although this concept has been controversial, it has permitted a set of predictions of the direction of future changes in these codons as the host develops its immune response and immunity of the population. Predicting the future changes in influenza strains provides a testable hypothesis and might then impact how we prepare for genetic drift in virus populations by designing vaccines.¹⁸⁴

The degeneracy of the genetic code means that there are different codons that encode the same amino acid. As a result, many sequences can encode the same protein. This choice of sequences is constricted by several selective forces such as restrictions on transfer RNA (tRNA) availability in a host, giving rise to preferential codon use, the overall G-C content of a genome, the frequency in which two or three amino acids appear next to each other in proteins encoded by the virus, or the avoidance of some sequence contexts due to a high mutational load.¹⁵⁸ The low level of CpG dinucleotides in some genomes may result because a C-residue can be methylated. This change is mutagenic because methyl-C will pair with a T residue, causing a C to T transition in the genome. Once these restrictions on the frequency of certain dinucleotide to septanucleotide sequences are appreciated, they can be factored into a calculation of whether certain nucleotide sequences are over-represented or under-represented in a genome despite these selected pressures observed in a particular genome.

Algorithms have been designed to accomplish this, and it is clear from an analysis of 209 prokaryotic genomes and 90 bacteriophages that replicate in these hosts, that selected sequences of di-septanucleotides are over-represented and others are under-represented in these viral and bacterial genomes.¹⁵⁷ Having factored out the genetic codon preferences in this algorithm, these preferences represent a second code of under- or over-represented frequencies of nucleotide sequences, and the available data indicate that these sequences are functional and are selected for over evolutionary time scales. First, coding regions of a genome have been shown to have different over- or under-represented sequences in a genome. Second, if these coding regions sequences are employed to assemble a phylogenetic tree, these sequences do an excellent job in reconstructing the known evolutionary relationships of these 209 prokaryotic genome sequences (done originally by aligning the ribosomal gene sequences). Third, about 80% of the viruses in these databases can be correctly assigned to their hosts by matching the over- and under-represented sequences in their viral and host genomes. The same selection pressure acting upon this second code in a host genome also acts upon the genomes of their parasites. We now await the application of this algorithm to the more complex genomes and viruses of eukaryotes. Host genomes contain an amazing number of viral or viral-related sequences. More than 50% of the DNA sequences found in the human genome were derived from retroviruses, retrotransposons, DNA transposons and randomly amplified sequences of genes (short interspersed nuclear element [SINES] and the 7S RNA gene), pseudogenes, and repetitive DNA sequences.^{114,192} Viruses certainly have left a major mark upon the evolution of their host's genomes in addition to the selective pressures they exert via virus infections and deaths. During the evolution of humans from their ancestral line, retroviruses and retro-transposons (the long interspersed nuclear element [LINE-1]) have entered the germ line, amplified their copy numbers, and integrated at various sites in the genome. This process introduces mutations, alters patterns of gene expression, and creates new interactions of viruses with their hosts. This is clearly one of the drivers of host evolution. Over time these retroviruses (human endogenous retroviruses, or HERVs) accumulate mutations in their genes, and some recombine out of the genome leaving only the long terminal repeats (LTRs) as a remnant marking their past insertion. Although humans no longer contain viable HERVs, the multiple copies of HERV-H or HERV-K viruses when transcribed in cells, produce functional viral proteins from different copies of these viruses, and the viral particles that are produced are defective and very poorly transmitted. Cellular transcription factors regulate the expression of the HERVs, and the p53 transcription factor (activated by stress and DNA damage) transcribes the HERV-H genome and produces particles in response to such stress.²⁰⁹ Similarly the LINE-1 retrotransposons, which have about 300 viable and movable elements in the human genome today, are responsible for about 1% of the mutations found in each generation. LINE-1 transposons also contain p53 DNA response elements⁸⁶ and thus are also regulated by stress responses recorded by the host. Although it is clear that retroviruses and transposons can shape the host genome, it is equally clear that the host genome is a place for new viral genomes to evolve, recombine with

exogenous viral genomes, and possibly produce a new agent optimized for replication in its host. Understanding of the dynamics of these vestiges of viruses that reside in our genome is a challenge for the future.

With many host-genome sequences representing all kingdoms of life in the databases, it has been possible to do some rather eye-opening analyses. For example, the resurrection of endogenous retroviruses from inactive sequences in host DNA has allowed the investigation of interactions between extinct pathogens called paleoviruses and their hosts that occurred millions of years ago.⁵³ By cloning these sequences, it has been possible to identify the cellular receptor of these extinct retroviruses.¹⁷² Perhaps more amazing is that similar "viral genome fossils" representing DNA copies of filoviruses and bornaviruses as well as parvoviruses and circoviruses have been found in a variety of host genomes.^{11,12} When the evolutionary history of various host genomes harboring these viral sequences were compared, it was possible to deduce that ancestors of modern viruses were in existence millions of years ago. What is even more curious is that these genome-insertion events seemed to happen around the same time in a wide variety of mammals. What global event could have stimulated such activities?

The Virome: How Many Viruses Are There? Where Are They? Why Are They There?

Virus ecology, as a result of modern virus discovery technology, is posing many questions (see 106,183). In 1977, when Fred Sanger sequenced the DNA genome of coliphage phiX174, many virologists were impressed with the wealth of information contained in a "simple" DNA sequence and the congruence of genetic and biochemical data with the genome structure. In fewer than 25 years, sampling, sequencing, and computer technology now provide the wherewithal to identify and sequence entire viral communities from their natural environment without the intervention of time-held techniques of isolation and characterization of individual viruses.^{48,178,194} In early 2003, a novel viral DNA microarray was used to reveal and partially sequence a previously uncharacterized coronavirus in a viral isolate cultured from a patient with SARS. This chip technology has advanced to the point that essentially all the known viral genomes can be represented on a single microarray. New techniques for discovery and analysis of viral populations are certain to be found. As can be expected in this "omics" era, the identification and study of an entire community of viruses in their natural habitat has been called metagenomics.^{2,156,202} The diversity of viruses in the environment is essentially unknown, as we have been limited to studying only those viruses that are easy to work with in the laboratory or those that have major impact on human health. The first metagenomic studies on viruses have revealed stunning diversity of genes and gene products that remain to be understood even in principle.^{178,203} The combination of host and bacteriophage genome sequencing in the bacteria has proved to be an exceptional window on genome evolution and gene transfer. The practical value of identifying new gene products with novel functions cannot be overestimated. The repertoire of tactics for gene control and regulation is far more extensive than any of us imagined before the era of metagenomics. We can only expect that as the metagenomics of animal and plant viruses advances,

the effect of knowing everything that is out there and the resulting knowledge of the dynamics of host–parasite interactions will be mind-boggling.¹⁷⁷

Pathogen Discovery

Historically, discovery of new viral pathogens followed identification of diseases of consequence to humans, animals, and plants. Field biologists, clinicians, veterinarians, and the lay public noted syndromes, unusual behaviors, or drastic changes of animal and plant populations, which motivated scientists to discover the cause. The early days of virology were all “translational research.” Koch’s postulates were developed to identify the causative agent for a given disease. Advances in virus identification were driven in large part by technology developments such as porcelain filters, animal models, tissue and cell culture, microscopic visualization of cytopathic effect, serology, immunoassays, hybridization, western blotting, PCR, sequencing, microarrays, and imaging technology. These advances paved the way to our current understanding of viral pathogens and provided the data to advance our current understanding of mechanisms of pathogenesis. Modern pathogen discovery has entered a new phase where via sequencing technology, virologists can detect and identify viral nucleic acids with unprecedented sensitivity in essentially any sample.¹²³ We no longer need to be able to grow a virus stock to be able to identify it and develop diagnostic reagents, vaccines, or antiviral drugs.

The discovery of new viral genomes is proceeding at an amazing pace.¹⁴³ Although the discovery process is straightforward, understanding what these viruses are doing is a serious challenge.^{91,155} If one finds novel viral genomes in samples from patients with disease, are these viruses the cause of the disease? Is it possible that they may be part of the normal flora of an individual (the microbiome;¹⁰⁷)? There are many populations of microbes in and on various parts of the body. Just identifying the microbiome differences in body sites of a single individual is challenging enough; cataloging the microbiome variation from individual to individual is even more difficult.¹⁵⁶ What functions does the microbiome have? There is evidence that our normal microbial flora stimulates local and systemic immune responses that protect against or suppress responses that contribute to pathogenesis by more-virulent microbes. Future virologists will have to unravel these heretofore unknown microbial relationships, and to do so we will need new technology. Whatever we find will undoubtedly reveal unanticipated insights about viruses and their hosts. Modern pathogen discovery will require the interaction of infectious disease specialists, epidemiologists, and bioinformatics specialists; virologists will have to be professionally “multilingual”.¹²¹

Perhaps of fundamental importance is that proof of causation can no longer rely on the time-honored Koch’s postulates.⁹¹ This assertion is made not only because it may be difficult to propagate new viruses and find models to test their pathogenicity, it also is likely that many diseases will involve the interaction of multiple microbial communities (viruses, bacteria, fungi) that will be difficult to reproduce in the laboratory. Pathogen discovery will require new biomarkers of health and disease, methods to improve sampling and stability of samples, technology to record relevant data, and

capacity to associate all this data with the sample. In the past, pathogen identification methods were slow and tedious, and working with multiple samples was difficult if not impossible. It is now possible to collect and analyze serial samples over time as patients move from health to disease. Assembling data, maintaining databases, and providing access for analysis will also involve advances in software and bioinformatics. In the end, the fundamental challenge will be how one moves from correlation of the presence of an agent or agents in disease to proof of causation.

Viruses are unique in nature. They are the smallest of all self-replicating organisms, historically characterized by their ability to pass through filters that retain even the smallest bacteria. In their most basic form, viruses consist solely of a small segment of nucleic acid encased in a simple protein shell. Viruses have no metabolism of their own but rather are obliged to invade cells and parasitize subcellular machinery, subverting it to their own purposes. Many have argued that viruses are not even living,¹²⁸ although to a seasoned virologist, they exhibit a life as robust as any other creature.

The apparent simplicity of viruses is deceptive. The truth is that as a group, viruses infect virtually every organism in nature, they display a dizzying diversity of structures and lifestyles, and they embody a profound complexity of function.

The study of viruses—virology—must accommodate both the uniqueness and the complexity of these organisms. The singular nature of viruses has spawned novel methods of classification and experimentation entirely peculiar to the discipline of virology. The complexity of viruses is constantly challenging scientists to adjust their thinking and their research to describe and understand some new twist in the central dogma revealed in a *simple* virus infection.

This chapter explores several concepts fundamental to virology as a whole, including virus taxonomy, virus cultivation

and assay, and virus genetics. The chapter is not intended as a comprehensive or encyclopedic treatment of these topics, but rather as a relatively concise overview with sufficient documentation for more in-depth study. In addition to primary resources and practical experience, the presentation draws heavily on previous editions of *Fields Virology*^{35–37} for the taxonomy and genetics material, plus several excellent texts for material on virus cultivation and assay.^{20,34,41,59,70,76,81} It is hoped that this chapter will be of value to anyone learning virology at any stage: a novice trying to understand basic principles for the first time, an intermediate student of virology trying to understand the technical subtleties of virological protocols in the literature, or a bewildered scientist in the laboratory wondering why the host-range virus mutant received from a colleague does not seem to manifest the described host range.

VIRUS TAXONOMY

A coherent and workable system of classification—a taxonomy—is a critical component of the discipline of virology. However, the unique nature of viruses has defied the strict application of many of the traditional tools of taxonomy used in other disciplines of biology. Thus, scientists who concern themselves with global taxonomy of organisms have traditionally either ignored viruses completely as nonliving entities or left them scattered throughout the major kingdoms, reasoning that viruses have more in common with their individual hosts than they do with each other.^{82,90} By contrast, for practical reasons at least, virologists agree that viruses should be considered together as a separate group of organisms regardless of host, be it plant, animal, fungus, protist, or bacterium, a philosophy borne out by the observation that in several cases viruses now classified in the same family—for example, family *Reoviridae*—infect hosts from different kingdoms. Interestingly, the discipline of virus taxonomy brings out the most erudite and thought-provoking, virtually philosophical discussions about the nature of viruses, probably because the decisions that must be made to distinguish one virus from another require the deepest thought about the nature of viruses and virus evolution. In the end, all of nature is a continuum, and the business of taxonomy has the unfortunate obligation of drawing boundaries within this continuum, an artificial and illogical task but necessary nevertheless. The execution of this obligation results today in a free-standing virus taxonomy, overseen by the International Committee on Taxonomy of Viruses (ICTV), with rules and tools unique to the discipline of virology. The process of virus taxonomy that has evolved

uses some of the hierarchical nomenclature of traditional taxonomy, identifying virus species and grouping these into genera, genera into families, and families into orders, but at the same time, to cope with both the uniqueness and diversity of viruses as a group, the classification process has been deliberately nonsystematic and thus is “based upon the opinionated usage of data”.⁹²

Most importantly, the virus taxonomy that has been developed works well. For the trained virologist, the mention of a virus family or genus name, such as “family *Herpesviridae*” or “genus *Rotavirus*” immediately conjures forth a set of characteristics that form the basis for further discussion or description. Virus taxonomy serves an important practical purpose as well, in that the identification of a limited number of biological characteristics, such as virion morphology, genome structure, or antigenic properties, quickly provides a focus for identification of an unknown agent for the clinician or epidemiologist and can significantly impact further investigation into treatment or prevention of a virus disease. Virus taxonomy is an evolving field, and what follows is a summary of the state of the art, including important historical landmarks that influenced the present system of virus taxonomy, a description of the system used for virus taxonomy and the means for implementation of that system, and a very brief overview of the taxonomy of viruses that infect humans and animals.

History and Rationale

Virology as a discipline is scarcely 100 years old, and thus the discipline of virus taxonomy is relatively young. In the early 1900s, viruses were initially classified as distinct from other organisms simply by virtue of their ability to pass through unglazed porcelain filters known to retain the smallest of bacteria. As increasing numbers of filterable agents became recognized, they were distinguished from each other by the only measurable properties available, namely the disease or symptoms caused in an infected organism. Therefore, animal viruses that caused liver pathology were grouped together as hepatitis viruses, and viruses that caused mottling in plants were grouped together as mosaic viruses. In the 1930s, an explosion of technology spawned a description of the physical properties of many viruses, providing numerous new characteristics for distinguishing viruses one from another. The technologies included procedures for purification of viruses, biochemical characterization of purified virions, serology, and perhaps most importantly, electron microscopy, in particular negative staining, which permitted detailed descriptions of virion morphology, even in relatively crude preparations of infected tissue. In the 1950s, these characterizations led to the distinction of three major animal virus groups, the myxoviruses, the herpesviruses, and the poxviruses. By the 1960s, because of the profusion of data describing numerous different viruses, it became clear that an organized effort was required to classify and name viruses, and thus the ICTV (originally the International Committee on Nomenclature of Viruses [ICNV]) was established in 1966. The ICTV functions today as a large, international group of virologists organized into appropriate study groups, whose charge it is to develop rules for the classification and naming of viruses and to coordinate the activities of study groups in the implementation of these rules.

Early in its history, the ICTV wrestled with the fundamental problem of developing a taxonomic system for classification and naming of viruses that would accommodate the unique properties of viruses as a group and that could anticipate advancements in the identification and characterization of viruses. Perhaps the most critical issue was whether the classification of viruses should consider virus properties in a monothetical, hierarchical fashion or a polythetical, hierarchical fashion. A *monothetic* system of classification is defined as a system based on a single characteristic or a series of single characteristics. *Polythetic* is defined as sharing several common characteristics without any one of these characteristics being essential for membership in the group or class in question. Thus, a monothetical, hierarchical classification, modeled after the Linnaean system used for classification of plants and animals, would effectively rank individual virus properties, such as genome structure or virion symmetry, as being more or less important relative to each other and use these individual characteristics to sort viruses into subphyla, classes, orders, suborders, and families.⁷⁹ Although the hierarchical ordering of viruses into groups and subgroups is desirable, a strictly monothetical approach to using virus properties in making assignments to groups was problematic because both the identification of individual properties to be used in the hierarchy and the assignment of a hierarchy to individual properties seemed too arbitrary. A polythetic approach to classification would group viruses by comparing simultaneously numerous properties of individual viruses without assigning a universal priority to any one property. Thus, using the polythetic approach, a given virus grouping is defined by a collection of properties rather than a single property, and virus groups in different branches of the taxonomy may be characterized by different collections of properties. One argument against the polythetic approach is that a truly systematic and comprehensive comparison of dozens of individual properties would be at least forbidding if not impossible. However, this problem could be avoided by the adoption of a nonsystematic approach, namely, using study groups of virologists within the ICTV to consider together numerous characteristics of a virus and make as rational an assignment to a group as possible. Therefore, the system that is currently being used is a nonsystematic, polythetical, hierarchical system. This system differs from any other taxonomic system in use for bacteria or other organisms; however, it is effective, useful, and has withstood the test of time.⁹¹ As our understanding of viruses increases, and as new techniques for characterization are developed, notably comparison of gene and genome sequences, the methods used for taxonomy will undoubtedly continue to evolve.

As a consequence of the polythetic approach to classification, the virus taxonomy that exists today has been filled initially from the middle of the hierarchy by assigning viruses to genera, and then elaborating the taxonomy upward by grouping genera into families and, to a limited extent, families into orders. By 1970, the ICTV had established two virus families each containing 2 genera, 24 floating genera, and 16 plant *groups*.¹³³ A rigorous species definition,¹²⁶ discussed later, was not approved by the ICTV until 1991 but has now been applied to the entire taxonomy and has become the primary level of classification for viruses. As of this writing, the currently accepted taxonomy recognizes 6 orders, 87 families, 19 subfamilies, 348 genera,

TABLE 2.1 Summary Characteristics of Vertebrate Virus Families

Family	Nucleocapsid morphology	Envelope	Virion morphology	Genome ^a	Host ^b
dsDNA viruses					
<i>Adenoviridae</i>	Icosahedral	No	Icosahedral	1 ds linear, 26–48 kb	V
<i>Alloherpesviridae</i>	Icosahedral	Yes	Spherical, tegument	2 ds linear, 135–294 kb	V
<i>Asfviridae</i>	Icosahedral	Yes ^c	Icosahedral	1 ds linear, 165–190 kb	V, I
<i>Herpesviridae</i>	Icosahedral	Yes	Spherical, tegument	1 ds linear, 125–240 kb	V
<i>Iridoviridae</i>	Icosahedral	No ^d	Icosahedral	1 ds linear, 140–303	V, I
<i>Papillomaviridae</i>	Icosahedral	No	Icosahedral	1 ds circular, 7–8 kb	V
<i>Polyomaviridae</i>	Icosahedral	No	Icosahedral	1 ds circular, 5 kb	V
<i>Poxviridae</i>	Ovoid	Yes	Ovoid	1 ds linear, 130–375 kb	V, I
ssDNA viruses					
<i>Anellovirus</i>	Icosahedral	No	Icosahedral	1 – circular, 2–4 kb	V
<i>Circoviridae</i>	Icosahedral	No	Icosahedral	1 – or ± circular, 2 kb	V
<i>Parvoviridae</i>	Icosahedral	No	Icosahedral	1 +, – or ± linear, 4–6 kb	V, I
dsDNA reverse transcribing viruses					
<i>Hepadnaviridae</i>	Icosahedral	Yes	Spherical	1 ds circular, 3–4 kb	V
ssRNA reverse transcribing viruses					
<i>Metaviridae</i>	Spherical	Yes	Spherical	1 + linear, 4–10 kb	F, I, P, V
<i>Retroviridae</i>	Spherical, rod or cone shaped	Yes	Spherical	1 + linear dimer, 7–13 kb	V
dsRNA viruses					
<i>Birnaviridae</i>	Icosahedral	No	Icosahedral	2 ds linear, 5–6 kb	V, I
<i>Picobirnaviridae</i>	Icosahedral	No	Icosahedral	3 ds linear, 4 kb	V
<i>Reoviridae</i>	Icosahedral	No	Icosahedral, layered	10–12 ds linear, 19–32 kb	V, I, P, F
Negative sense ssRNA viruses					
<i>Bornaviridae</i>	ND ^e	Yes	Spherical	1 – linear, 9 kb	V
<i>Deltavirus^f</i>	Isometric	Yes	Spherical	1 – circular, 2 kb	V
<i>Filoviridae</i>	Helical filaments	Yes	Bacilliform, filamentous	1 – linear, 19 kb	V
<i>Orthomyxoviridae</i>	Helical filaments	Yes	Pleomorphic, spherical	6–8 – linear, 10–15 kb	V
<i>Paramyxoviridae</i>	Helical filaments	Yes	Pleomorphic, spherical, filamentous	1 – linear, 13–18 kb	V
<i>Rhabdoviridae</i>	Coiled helical filaments	Yes	Bullet shaped	1 – linear, 11–15 kb	V, I, P
Positive sense ssRNA viruses					
<i>Arteriviridae</i>	Linear, asymmetric	Yes	Spherical	1 + linear, 13–16 kb	V
<i>Astroviridae</i>	Icosahedral	No	Icosahedral	1 + linear, 6–8 kb	V
<i>Caliciviridae</i>	Icosahedral	No	Icosahedral	1 + linear, 7–8 kb	V
<i>Coronaviridae</i>	Helical	Yes	Spherical	1 + linear, 26–32 kb	V
<i>Flaviviridae</i>	Spherical	Yes	Spherical	1 + linear, 9–13 kb	V, I
<i>Hepevirus^g</i>	Icosahedral	No	Icosahedral	1 + linear, 7 kb	V
<i>Nodaviridae</i>	Icosahedral	No	Icosahedral	2 + linear, 4–5 kb	V, I
<i>Picornaviridae</i>	Icosahedral	No	Icosahedral	1 + linear, 7–9 kb	V
<i>Togaviridae</i>	Icosahedral	Yes	Spherical	1 + linear, 10–12 kb	V, I
Ambisense ssRNA viruses					
<i>Arenaviridae</i>	Filamentous	Yes	Spherical	2 ± linear, 11 kb	V
<i>Bunyaviridae</i>	Filamentous	Yes	Spherical	3 – or ± linear, 11–19 kb	V, I, P
Subviral agents: prions					
Prions	—	—	—	—	V, F

^aNumber of segments, polarity (ds, double stranded; +, mRNA like; –, cRNA like; ±, ambisense), conformation, size.

^bV, vertebrate; P, plant; I, insect; F, fungus.

and 2,290 species. The complete virus taxonomy is far too extensive to relate here; however, examples of the results of the taxonomy are offered in Tables 2.1 and 2.2. Table 2.1 lists the distinguishing characteristics of the vertebrate animal virus families, whereas Table 2.2 provides an example of the entire taxonomic classification of one virus order, namely order *Mononegavirales*.

The International Committee on Taxonomy of Viruses Universal System of Virus Taxonomy

Structure and Function

The ICTV is a committee of the Virology Division of the International Union of Microbiological Societies. The objectives of the ICTV are to develop an internationally agreed taxonomy

TABLE 2.2 Taxonomy of the Order *Mononegavirales*

Order	Family	Subfamily	Genus	Type species	Host
<i>Mononegavirales</i>	<i>Bornaviridae</i>		<i>Bornavirus</i>	<i>Borna disease virus</i>	V
			<i>Vesiculovirus</i>	<i>Vesicular stomatitis Indiana virus</i>	V, I
	<i>Rhabdoviridae</i>		<i>Lyssavirus</i>	<i>Rabies virus</i>	V
			<i>Ephemerovirus</i>	<i>Bovine ephemeral fever virus</i>	V, I
			<i>Novirhabdovirus</i>	<i>Infectious hematopoietic necrosis virus</i>	V
			<i>Cytorhabdovirus</i>	<i>Lettuce necrotic yellows virus</i>	P, I
			<i>Nucleorhabdovirus</i>	<i>Potato yellow dwarf virus</i>	P, I
	<i>Filoviridae</i>		<i>Marburgvirus</i>	<i>Lake Victoria marburgvirus</i>	V
			<i>Ebolavirus</i>	<i>Zaire ebolavirus</i>	V
	<i>Paramyxoviridae</i>	<i>Paramyxovirinae</i>	<i>Rubulavirus</i>	<i>Mumps virus</i>	V
			<i>Avulavirus</i>	<i>Newcastle disease virus</i>	V
			<i>Respirovirus</i>	<i>Sendai virus</i>	V
			<i>Henipavirus</i>	<i>Hendra virus</i>	V
			<i>Morbillivirus</i>	<i>Measles virus</i>	V
		<i>Pneumovirinae</i>	<i>Pneumovirus</i>	<i>Human respiratory syncytial virus</i>	V
			<i>Metapneumovirus</i>	<i>Avian metapneumovirus</i>	V

V, vertebrate; I, insect; P, plant.

and nomenclature for viruses, to maintain an index of virus names, and to communicate the proceedings of the committee to the international community of virologists. The ICTV publishes an update of the taxonomy at approximately 3-year intervals.^{32,33,39,85,86,92,133} At the time of this writing, the ninth report is being completed. The official taxonomy is also available on line at the ICTV website: <http://www.ictvonline.org>.

Virus Properties and Their Use in Taxonomy

As introduced previously, the taxonomic method adopted for use in virology is polythetic, meaning that any given virus group is described using a collection of individual properties. The description of a virus group is nonsystematic in that there exists no fixed list of properties that must be considered for all viruses and no strict formula for the ordered consideration of properties. Instead, a set of properties describing a given virus is simply compared with other viruses described in a similar fashion to formulate rational groupings. Characters such as virion morphology, genome organization, method of replication, and the number and size of structural and nonstructural viral proteins are used for distinguishing different virus families and genera. Characters such as genome sequence relatedness, natural host range, cell and tissue tropism, pathogenicity and cytopathology, mode of transmission, physicochemical properties of virions, and antigenic properties of viral proteins are used for distinguishing virus species within the same genus.¹²⁷

The Hierarchy

The ICTV has adopted a universal classification scheme that employs the hierarchical taxonomic levels of order, family, subfamily, genus, and species. Because the polythetic approach to classification introduces viruses into the middle of the hier-

archy, and because the ICTV has taken a relatively conservative approach to grouping taxa, levels higher than order are not currently used. Interestingly, groupings above the level of order may prove to be inappropriate: Higher taxons imply a common ancestry for viruses, whereas multiple independent lineages for viruses now seems the more likely evolutionary scenario.³² Taxonomic levels lower than species, such as clades, strains, and variants, are not officially considered by the ICTV but are left to specialty groups.

A virus species is defined as “a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche”.¹²⁶ The formal definition of a polythetic class is “a class whose members always have several properties in common although no single common attribute is present in all of its members”.¹²⁷ Thus, no single property can be used to define a given species, and application of this formal definition of a polythetic class to species accounts nicely for the inherent variability found among members of a species. The qualification of a replicating lineage implies that members of a species experience evolution over time with consequent variation, but that members share a common ancestor. The qualification of occupation of an ecological niche acknowledges that the biology of a virus, including such properties as host range, pathogenesis, transmission, and habitat, are fundamental components of the characterization of a virus. A *type species* has been identified for each genus. The type species is not necessarily the best characterized or most representative species in a genus; rather, it is usually the virus that initially necessitated the creation of the genus and therefore best defines or identifies the genus.

Taxonomic levels higher than species are formally defined by the ICTV only in a relative sense, namely a genus is a group of species sharing certain common characters, a subfamily is a group of genera sharing certain common characters, a family is a group of genera or subfamilies

sharing certain common characters, and an order is a group of families sharing certain common characters. As the virus taxonomy has evolved, these higher taxa have acquired some monothetic character. They remain polythetic in that they may be characterized by more than one virus property; however, they violate the formal definition of a polythetic class in that one or more defining properties may be required of all candidate viruses for membership in the taxon. Not all taxonomic levels need be used for a given grouping of viruses, thus whereas most species are grouped into genera and genera into families, not all families contain subfamilies, and only a few families have been grouped into orders. Consequently, the family is the highest consistently used taxonomic grouping, it therefore carries the most generalized description of a given virus group, and as a result has become the benchmark of the taxonomic system. Most families have distinct virion morphology, genome structure, and/or replication strategy (see Table 2.1).

Nomenclature

The ICTV has adopted a formal nomenclature for viruses, specifying suffixes for the various taxa, and rules for written descriptions of viruses. Names for genera, subfamilies, families, and orders must all be single words, ending with the suffixes -virus, -virinae, -viridae, and -virales, respectively. Species names may contain more than one word and have no specific ending. In written usage, the formal virus taxonomic names are capitalized and written in italics, and preceded by the name of the taxon, which is neither capitalized nor italicized. For

species names that contain more than one word, the first word plus any proper nouns are capitalized. As an example, the full formal written description of human respiratory syncytial virus is as follows: order *Mononegavirales*, family *Paramyxoviridae*, subfamily *Pneumovirinae*, genus *Pneumovirus*, species *Human respiratory syncytial virus*. The ICTV acknowledges that vernacular (informal) taxonomic names are widely used; however, they should not be italicized or capitalized. For example, the vernacular name “herpesvirus” refers to a member of the family *Herpesviridae*.

Informal Groupings and Alternate Classification Schemes

For convenience in presenting or tabulating the virus taxonomy, informal categorical groupings of taxa are often used. The criteria applied for such groupings typically include nature of the viral genome (DNA or RNA), strandedness of the viral genome (single stranded or double stranded), polarity of the genome (positive sense, negative sense, or ambisense), and reverse transcription. Separate categories accommodate subviral agents (including viroids, satellites, and prions) and unassigned viruses. The Baltimore classification system, named after its creator David Baltimore, is a widely used scheme based on the nature of the genome packaged in virions and the pathway of nucleic acid synthesis that each group takes to accomplish messenger RNA (mRNA) synthesis.¹ This classification divides viruses into seven categories as depicted in Figure 2.1. Most usages of this system group ambisense virus families (family *Arenaviridae*

FIGURE 2.1. The Baltimore classification, a virus classification scheme based on the form of nucleic acid present in virion particles and the pathway for expression of the genetic material as messenger RNA.¹

The original scheme contained groups I through VI and has been expanded to accommodate DNA-containing, reverse transcribing viruses. Viruses containing ambisense single-stranded RNA genomes are grouped under negative sense single-stranded RNA viruses. (Reprinted from Hulo C, de Castro E, Masson P, et al. ViralZone: a knowledge resource to understand virus diversity. *Nucleic Acids Res* 2011;39 (Database issue):D576–D582; ViralZone, Swiss Institute of Bioinformatics, <http://www.expasy.ch/viralzone/>, with permission.)

and family *Bunyaviridae*) along with negative sense, single-stranded RNA (ssRNA) viruses. The families of vertebrate viruses listed in Table 2.1 have been grouped according to the Baltimore classification, with ambisense viruses split into an eighth genome category.

Universal Virus Database

To facilitate the management and distribution of virological data, the ICTV has established the universal virus database of the ICTV (ICTVdB). The ICTVdB is accessible on the Internet at <http://www.ictvdb.org>. Constructed from virus descriptions in the published reports of the ICTV, the database comprises searchable descriptions of all virus families, genera, and type species, including microscopic images of many viruses. The ICTVdB is a powerful resource for management of and access to virological data, and promises to considerably extend the reach and capability of the ICTV.

VIRUS CULTIVATION AND ASSAY

Different branches of science are defined in large part by their techniques, and virology is no exception. Whereas the study of viruses uses some general methods that are common to other disciplines, the unique nature of viruses and virus infections requires a unique set of technical tools designed specifically for their investigation. Conversely, what we know and *can* know about viruses is delimited by the techniques used; therefore, a genuine understanding of virology requires a clear understanding of virological methods. What follows is a summary of the major techniques essential and unique to all of virology, presented as fundamental background for understanding the discipline.

Initial Detection and Isolation

The presence of a virus is evidenced initially by effects on a host organism or, in the case of a few animal viruses, by effects on cultured cells. Effects on animal hosts obviously include a broad spectrum of symptoms, including skin and mucous membrane lesions; digestive, respiratory, or neurological disorders; immune dysfunction; specific organ failure such as hepatitis or myocarditis; and death. Effects on cultured cells include a variety of morphological changes in infected cells, termed *cytopathic effects* and described in detail later in this chapter and in Chapter 15. Both adenovirus¹⁰⁸ and the polyomavirus SV40¹²¹ were discovered as cell culture contaminants before they were detected in their natural hosts.

Viruses can be isolated from an infected host by harvesting excreted or secreted material, blood, or tissue and testing for induction of the original symptoms in the identical host, or induction of some abnormal pathology in a substitute host or in cell culture. Historically, dogs, cats, rabbits, rats, guinea pigs, hamsters, mice, and chickens have all been found to be useful in laboratory investigations,⁷⁰ although most animal methods have now been replaced by cell culture methods.⁸¹ Once the presence of a virus has been established, it is often desirable to prepare a genetically pure clone, either by limiting serial dilution or by plaque purification.

Viruses that are cultivated in anything other than the natural host may adapt to the novel situation through acquisition

of genetic alterations that provide a replication advantage in the new host. Such adaptive changes may be accompanied by a loss of fitness in the original host, most notably by a loss of virulence or pathogenicity. Whereas this adaptation and attenuation may present problems to the basic scientist interested in understanding the replication of the virus in its natural state, it also forms the basis of construction of attenuated viral vaccines.

Hosts for Virus Cultivation

Laboratory Animals and Embryonated Chicken Eggs

Prior to the advent of cell culture, animal viruses could be propagated only on whole animals or embryonated chicken eggs. Whole animals could include the natural host or laboratory animals such as rabbits, mice, rats, and hamsters. In the case of laboratory animals, newborn or suckling rodents often provide the best hosts. Today, laboratory animals are seldom used for routine cultivation of virus; however, they still play an essential role in studies of viral pathogenesis.

The use of embryonated chicken eggs was introduced to virology by Goodpasture et al⁴⁴ in 1932 and developed subsequently by Beveridge and Burnet.⁴ The developing chick embryo, 10 to 14 days after fertilization, provides a variety of differentiated tissues, including the amnion, allantois, chorion, and yolk sac, which serve as substrates for growth of a wide variety of viruses, including orthomyxoviruses, paramyxoviruses, rhabdoviruses, togaviruses, herpesviruses, and poxviruses.⁷⁰ Members of each of these virus families may replicate in several tissues of the developing egg, or replication may be confined to a single tissue. Several viruses from each of the previously mentioned groups cause discrete and characteristic foci when introduced onto the chorioallantoic membrane of embryonated eggs, thus providing a method for identification of virus types, or for quantifying virus stocks or assessing virus pathogenicity (Fig. 2.2). Although embryonated eggs have been almost wholly replaced by cell culture techniques, they are still the most convenient method for growing high titer stocks of some viruses and thus continue to be used both in research laboratories and for vaccine production.

Cell Culture

The growth and maintenance of animal cells *in vitro*, described generally (albeit incorrectly) as tissue culture, can be formally divided into three different techniques: organ culture, primary explant culture, and cell culture. In *organ culture*, the original three-dimensional architecture of a tissue is preserved under culture conditions that provide a gas-liquid interface. In *primary explant culture*, minced pieces of tissue placed in liquid medium in a culture vessel provide a source for outgrowth of individual cells. In *cell culture*, tissue is disaggregated into individual cells prior to culturing. Only cell culture will be discussed in detail here, because it is the most commonly used tissue culture technique in virology.

Cultured cells currently provide the most widely used and most powerful hosts for cultivation and assay of viruses. Cell cultures are of three basic types—primary cell cultures, cell strains, and cell lines—that may be derived from many animal species and that differ substantially in their characteristics. Viruses often behave differently on different types of cultured cells; in addition, each of the culture types possess technical

FIGURE 2.2. Cowpox-induced pock formation on the chorioallantoic membrane of chick embryos. The chorioallantoic membrane of intact chicken embryos, 11 days old, were inoculated with cowpox, and the eggs were incubated for an additional 3 days at 37.5°C. Chorioallantoic membranes were then dissected from the eggs and photographed. The membrane shown in **A** was untreated, whereas the membrane in **B** was stained with NBT, an indicator of activated heterophils.⁴⁰ Wild-type cowpox forms red hemorrhagic pocks on the membrane (**A** and **B**). Spontaneous deletion mutants of cowpox virulence genes occur at a high frequency, resulting in infiltration of inflammatory cells into the pock. The infiltration of inflammatory cells causes the pocks to appear white in unstained membrane preparations or dark blue on NBT-stained membranes. The unstained membrane preparation (**A**) contains a single white pock, whereas the NBT-stained preparation (**B**) contains a single blue pock. NBT, nitroblue tetrazolium. (Courtesy of Dr. R. Moyer.)

advantages and disadvantages. For these reasons, an appreciation of the use of cultured cells in animal virology requires an understanding of several fundamentals of cell culture itself. A detailed description of the theory and practice of cell and tissue culture is provided by Freshney,⁴¹ and several additional texts provide excellent summaries of cell culture as it specifically applies to virology.^{20,34,59}

PRIMARY CELL CULTURE

A primary cell culture is defined as a culture of cells obtained from the original tissue that have been cultivated *in vitro* for the first time and that have not been subcultured. Primary

cell cultures can be established from whole animal embryos or from selected tissues from embryos, newborn animals, or adult animals of almost any species. The most commonly used cell cultures in virology derive from primates, including humans and monkeys; rodents, including hamsters, rats, and mice; and birds, most notably chickens. Cells to be cultured are obtained by mincing tissue and dispersing individual cells by treatment with proteases and/or collagenase to disrupt cell–cell interactions and interactions of cells with the extracellular matrix. With the exception of cells from the hemopoietic system, normal vertebrate cells will grow and divide only when attached to a solid surface. Dispersed cells are therefore placed in a plastic flask or dish, the surface of which has been treated to promote cell attachment. The cells are incubated in a buffered nutrient medium in the presence of blood serum, which contains a complex mixture of hormones and factors required for the growth of normal cells. The blood serum may come from a variety of sources, although bovine serum is most commonly used. Under these conditions, cells will attach to the surface of the dish, and they will divide and migrate until the surface of the dish is covered with a single layer of cells, a monolayer, whereupon they will remain viable but cease to divide. If the cell monolayer is “wounded” by scraping cells from an isolated area, cells on the border of the wound will resume division and migration until the monolayer is reformed, whereupon cell division again ceases. These and other observations lead to the conclusion that the arrest of division observed when cells reach confluency results from cell–cell contact and therefore is called *contact inhibition*. Primary cultures may contain a mixture of cell types and retain the closest resemblance to the tissue of origin.

SUBCULTIVATION

Cells from a primary culture may be subcultured to obtain larger numbers of cells. Cells are removed from the culture dish and disaggregated by treating the primary cell monolayer with a chelating agent, usually EDTA, or a protease, usually trypsin, or both, giving rise to a single cell suspension. This suspension is then diluted to a fraction of the original monolayer cell density and placed in a culture dish with fresh growth medium, whereupon the cells attach to the surface of the dish and resume cell division until once again a monolayer is formed and cell division ceases. Cultures established in this fashion from primary cell cultures may be called *secondary cultures*. Subsequently, cells may be repeatedly subcultured in the same fashion. Each subculturing event is called a *passage*, and each passage may comprise several cell generations, depending on the dilution used during the passage. Most vertebrate cells divide at the rate of approximately one doubling every 24 hours at 37°C. Thus, a passage performed with an eightfold dilution will require three cell doublings over 3 days before the cells regain confluency.

CELL STRAINS

Normal vertebrate cells cannot be passaged indefinitely in culture. Instead, after a limited number of cell generations, usually 20 to 100 depending on the age and species of the original animal, cultured normal cells cease to divide, then degenerate and die, a phenomenon called *crisis* or *senescence*⁵¹ (Fig. 2.3). Starting with the establishment of a secondary culture and until cells either senesce or become transformed as described later, the culture is termed a *cell strain* to distinguish it from a primary culture

FIGURE 2.3. Growth of cells in culture. A primary culture is defined as the original plating of cells from a tissue, grown to a confluent monolayer, without subculturing. A cell strain (*solid line*) is defined as a euploid population of cells subcultivated once or more *in vitro*, lacking the property of indefinite serial passage. Cell strains ultimately undergo degeneration and death, also called *crisis* or *senescence*. A cell line (*dashed line*) is an aneuploid population of cells that can be grown in culture indefinitely. Spontaneous transformation or alteration of a cell strain to an immortal cell line can occur at any time during cultivation of the cell strain. The time in culture and corresponding number of subcultivations or passages are shown on the abscissas. The ordinate shows the total number of cells that would accumulate if all were retained in culture. (Reprinted from *Animal cells: cultivation, growth regulation, transformation*. In: Davis BD, Dulbecco R, Eisen HN, et al, eds. *Microbiology*. 4th ed. Philadelphia: J. B. Lippincott Company.)

on the one hand, or a transformed, immortal cell line on the other hand. During culture, cells in a strain retain their original karyotype and are thus called *euploid*; however, culturing induces profound changes in the composition and characteristics of the cell strain, which are manifested early during the passage history and may continue during passage. Whereas primary cell cultures may contain a mixture of cell types that survive the original plating of cells, only a few cell types survive subculturing; thus, by

the second or third passage, typically only one cell type remains in the cell strain. Cell strains are usually composed of one of two basic cell types—fibroblast-like or epithelial-like—characterized based on their morphology and growth characteristics (Fig. 2.4). Fibroblasts have an elongated, spindle shape, whereas epithelial cells have a polygonal shape. Although after only a few passages only one cell type may remain in a cell strain, continued passage may select for faster-growing variants, such that the

FIGURE 2.4. Cultured cell types. Phase contrast photomicrographs are shown. **A:** Epithelial-like cells, A549, a human lung carcinoma cell line, a slightly subconfluent monolayer. **B:** Fibroblast-like cells, BHK, a baby hamster kidney cell line. characteristics of a cell strain may change with increasing passage number. Despite the fact that normal cell strains experience senescence in culture, they may be maintained for many years by expanding the culture to a large number of cells early during the passage history and storing numerous small samples of low passage cells by freezing. Therefore, as a given strain approaches high passage number and senescence, low passage cells of the same strain may be thawed and cultured.

CELL LINES

At any time during the culture of a cell strain, cells in the culture may become *transformed* such that they are no longer subject to crisis and senescence but can be passaged indefinitely. Transformation is a complex phenomenon, discussed in more detail later and in Chapter 7; however, in the context of cell culture, the most important characteristic of transformation is that the transformed cells become immortalized. Immortal cell cultures are called *cell lines*, or sometimes *continuous cell lines*, to distinguish them from primary cultures and cell strains. Immortalization can occur spontaneously during passage of a cell strain, or it can be induced by treatment with chemical mutagens, infection with tumorigenic viruses, or transfection with oncogenes. In addition, cells cultured from tumor tissue frequently readily establish immortal cell lines in culture. Spontaneous immortalization does not occur in cultured cells from all animal species. Thus, immortalization occurs frequently during culture of rodent cells (e.g., in mouse and hamster cell strains), and it has been observed in monkey kidney cells, although it occurs rarely, if at all, during the culture of chicken or human cells. Immortalization is typically accompanied by genetic changes such that cells become aneuploid, containing abnormalities in the number and structure of chromosomes relative to the parent species, and not all cells in a culture of a continuous cell line necessarily display the same karyotype. Like cell strains, cell lines are usually composed of cells that are either fibroblast-like or epithelial-like in morphology.

As with the propagation of cell strains, continued culture of a cell line may result in selection of specific variants that outgrow other cells in the culture over time, and thus with passage the character of a cell line may change substantially, and cell lines of the same origin cultured in different laboratories over a period of years may have significantly different characteristics. It is prudent, therefore, to freeze stocks of cell lines having specific desirable properties so that these cells can be recovered if the properties disappear during culture. Likewise, it makes sense to obtain a cell line showing certain desired characteristics directly from the laboratory that described those characteristics, because cells from alternate sources may differ in character.

TRANSFORMATION

Transformed cells are distinguished from normal cells by myriad properties that can be grouped into three fundamental types of changes: immortalization, aberrant growth control, and malignancy. *Immortalization* refers simply to the ability to be cultured indefinitely, as described previously. *Aberrant growth control* comprises a number of properties, several of which have relevance to experimental virology, including loss of contact inhibition, anchorage independence, and tumorigenicity. Loss of contact inhibition means that cells no longer cease to grow as soon as a monolayer is formed, and cells will now grow on top of one another. Anchorage independence means that the cells no longer need to attach to a solid surface

to grow. Anchorage independence is often assayed as the ability to form colonies suspended in a semisolid medium such as agar, and a practical consequence of anchorage independence is the ability to grow in liquid suspension. Tumorigenicity refers to the ability of cells to form a tumor in an experimental animal, and *malignancy* refers to the ability to form an invasive tumor *in vivo*. While malignancy is obviously of vital importance as a phenomenon in its own right, it has limited application in virology except within the specific discipline of tumor virology (Chapter 7). Importantly, the many properties of transformed cells are not necessarily interdependent, and no one property is an absolute prerequisite for another. Thus, transformation is thought to be a multistep genetic phenomenon, and varying degrees of transformation are measurable. Tumorigenicity is often regarded as the most stringent assay for a fully transformed cell and is most closely correlated with anchorage independence.

The fact that the various characteristics of transformed cells are not interdependent has important consequences for experimental virology, especially in the assay of tumor viruses. Specifically, a transformed cell line that is immortalized but still contact inhibited may be used in a viral transformation assay that measures the further transformation to loss of contact inhibition. When cells in a monolayer are transformed by a tumor virus and lose contact inhibition, they grow on top of a confluent monolayer, forming a *focus*, literally a pile of cells, which is readily distinguishable from the rest of the monolayer. This property forms the basis for quantitative biological assay of tumor viruses,¹²⁹ described in more detail later.

ADVANTAGES AND DISADVANTAGES OF DIFFERENT CULTURED CELL TYPES

The various types of cultured cells described previously have specific application to different problems encountered in experimental virology. For most applications, an adherent cell line provides the most useful host cell. Cell lines are relatively easy to maintain because they can be passaged indefinitely, and adherence is a prerequisite for a plaque assay, described later. A distinct technical advantage of adherent cells is that the culture medium can easily be changed for the purposes of infection or metabolic labeling by simply aspirating and replacing fluid from a monolayer, a process that requires repeated centrifugations with suspension cells. By contrast, relative to adherent cell lines, suspension cell lines are easier to sample than adherent cells, and they produce large numbers of cells from a relatively small volume of medium in a single culture vessel, which has significant advantages for some high-volume applications in virology. Unfortunately, not all viruses will grow on a cell line, and often under these circumstances, a primary cell culture will suffice. This may reflect a requirement for a particular cell type found only under conditions of primary cell culture, or it may reflect a requirement for a state of metabolism or differentiation closely resembling the *in vivo* situation, which is more likely to exist in a primary culture than it is in a cell line.

Lastly, some viruses do not grow in cell culture at all. In such cases, investigators are reliant either on the old expedients of natural hosts, laboratory animals, or embryonated eggs, or on some more modern advances in tissue culture and recombinant DNA technology. The papillomaviruses, which cause warts, provide an enlightening example of this situation (Chapter 54). Although the viral nature of papillomatosis was

demonstrated more than 90 years ago, progress on the study of papillomaviruses was seriously hampered in the virology heyday of the mid 20th century because the viruses grow well only on the natural host; they do not grow in culture. The inability to grow in culture is now reasonably well understood, and results from a tight coupling of the regulation of viral gene expression with the differentiation state of the target epithelial cell, which in turn is tightly coupled to the three-dimensional architecture of the epidermis, which is lost in culture. Specialized tissue culture techniques have now been developed that result in the faithful reconstruction of an epidermis by seeding primary keratinocytes on a “feeder” layer composed of an appropriate cell line and incubating these cells on a “raft” or grid at a liquid–air interface. On these raft cultures, the entire replication cycle of a papillomavirus can be reproduced *in vitro*, albeit with difficulty.⁷ In the meantime, it is significant that a large fraction of the genetics and biology of papillomaviruses was determined primarily through the use of recombinant DNA technology, without ever growing virus in culture. Thus, the genetic structure of both the model bovine papillomavirus and many human papillomaviruses has been determined by cloning genomic DNA from natural infections, and regulation and function of many genes can be gleaned from sequence alone, from *in vitro* assays on individual gene products expressed *in vitro*, and from cell transformation assays that use all or parts of a papillomavirus genome. In summary, the inability to grow a virus in culture, although it increases the challenge, no longer presents an insurmountable impediment to understanding a virus.

Recognition of Viral Growth in Culture

Two principal methods exist for the recognition of a virus infection in culture: cytopathic effect and hemadsorption. *Cytopathic effect* comprises two different phenomena: (a) morphological changes induced in individual cells or groups of cells by virus infection that are easily recognizable under a light microscope, and (b) inclusion bodies, which are more subtle alterations to the intracellular architecture of individual cells. *Hemadsorption* refers to indirect measurement of viral protein synthesis in infected cells, detected by adsorption of erythrocytes to the surface of infected cells. Cytopathic effect is the simplest and most widely used criterion for infection; however, not all viruses cause a cytopathic effect, and in these cases, other methods must suffice.

Morphological changes induced by virus infection comprise a number of cell phenomena, including rounding, shrinkage, increased refractility, fusion, aggregation, loss of adherence or lysis. Morphological changes caused by a given virus may include several of these phenomena in various combinations, and the character of the cytopathic effect may change reproducibly during the course of infection. Morphological changes caused by a given virus are very reproducible and can be so precisely characteristic of the virus type that significant clues to the identity of a virus can be gleaned from the cytopathic effect alone (Chapter 15). Figure 2.5 depicts different cytopathic effects caused by two viruses—measles and vaccinia. Most important to the trained virologist, a simple microscopic examination of a cell culture can reveal whether an infection is present, what fraction of cells are infected, and how advanced the infection is. In addition, because cytopathology results directly from the action of virus gene products, virus mutants can be obtained that are

altered in cytopathology, yielding either a conveniently marked virus or a tool to study cytopathology *per se*.

The term *inclusion bodies* refers generally to the observation of intracellular structures specific to an infected cell and discernible by light microscopy. The effects are highly specific for a particular virus type so that, as with morphological alterations, the presence of a specific type of inclusion body can be diagnostic of a specific virus infection. Electron microscopy, combined with a more detailed understanding of the biology of many viruses, reveals that inclusion bodies usually represent focal points of virus replication and assembly, which differ in appearance depending on the virus. For example, Negri bodies formed during a rabies virus infection represent collections of virus nucleocapsids⁸⁴ (Chapter 31).

Hemadsorption refers to the ability of red blood cells to attach specifically to virus-infected cells.¹¹¹ Many viruses synthesize cell attachment proteins, which carry out their function wholly or in part by binding substituents such as sialic acid that are abundant on a wide variety of cell types, including erythrocytes. Often, these viral proteins are expressed on the surface of the infected cell—for example, in preparation for maturation of an enveloped virus through a budding process. Thus, a cluster of infected cells may be easily detectable to the naked eye as areas that stain red after exposure to an appropriate preparation of red blood cells. Hemadsorption can be a particularly useful assay for detecting infections by viruses that cause little or no cytopathic effect.

Virus Cultivation

From the discussion presented previously, it may be obvious that ultimately the exact method chosen for growing virus on any particular occasion will depend on a variety of factors, including (a) the goals of the experiment, namely whether large amounts of one virus variant or small amounts of several variants are to be grown; (b) limitations in the *in vitro* host range of the virus, namely whether it will grow on embryonated eggs, primary cell cultures, continuous adherent cell lines, or suspension cell lines; and (c) the relative technical ease of alternative possible procedures. Furthermore, the precise method for harvesting a virus culture will depend on the biology of the virus—for example, whether it buds from the infected cell, lyses the infected cell, or leaves the cell intact and stays tightly cell associated. As a simple example, consider cultivation of a budding, cytopathic virus on an adherent cell line. Confluent monolayers of an appropriate cell line are exposed to virus diluted to infect a fraction of the cells, and progress of the infection is monitored by observing the development of the cytopathic effect until the infection is judged complete based on experience with the relationship between cytopathic effect and maximum virus yield. A crude preparation of virus can be harvested simply by collecting the culture fluid; it may not even be necessary to remove cells or cell debris. Most viruses can be stored frozen indefinitely either as crude or purified, concentrated preparations.

Quantitative Assay of Viruses

Two major types of quantitative assays for viruses exist: physical and biological. *Physical* assays, such as hemagglutination, electron microscopic particle counts, optical density measurements, or immunological methods, quantify only the presence of virus particles whether or not the particles are infectious. *Biological* assays, such as the plaque assay or various endpoint

FIGURE 2.5. Virus-induced cytopathic effects. Phase contrast photomicrographs are shown. **A:** Uninfected A549 cells, a human lung carcinoma cell line. **B:** A549 cells infected with measles virus at a moi of less than 0.01 pfu/cell. Individual plaques can be discerned. Measles fuses cells, causing formation of syncytia. In mid field is a large syncytium containing multiple nuclei. Surrounding this area are additional syncytia, including two that have rounded and are separating from the dish. **C:** Uninfected BSC40 cells, an African green monkey cell line. **D:** BSC40 cells infected with vaccinia virus at a moi of less than 0.01 pfu/cell. A single plaque is shown in the middle of the field. **E:** BSC40 cells infected with vaccinia virus at a moi of 10 pfu/cell, 48 hours after infection. All cells are infected and display complete cytopathic effect. (Cultures of vaccinia infections courtesy of J. I. Lewis. Cultures of measles infections courtesy of S. Smallwood and Dr. S. Moyer.)

methods that have in common the assay of infectivity in cultured cells or *in vivo*, measure only the presence of infectivity and may not count all particles present in a preparation, even many that are in fact infectious. Thus, a clear understanding of the nature and efficiency of both physical and biological quantitative virus assays is required to make effective use of the data obtained from any assay.

Biological Assays

THE PLAQUE ASSAY

The plaque assay is the most elegant, the most quantitative, and the most useful biological assay for viruses. Developed originally for the study of bacteriophage by d'Herelle¹⁸ in the early 1900s, the plaque assay was adapted to animal viruses by Dulbecco and Vogt²⁸ in 1953, an advance that revolutionized animal virology by introducing a methodology that was

relatively simple and precisely quantitative, which enabled the cloning of individual genetic variants of a virus, and which permitted a qualitative assay for individual virus variants that differ in growth properties or cytopathology.

The plaque assay is based simply on the ability of a single infectious virus particle to give rise to a macroscopic area of cytopathology on an otherwise normal monolayer of cultured cells. Specifically, if a single cell in a monolayer is infected with a single virus particle, new virus resulting from the initial infection can infect surrounding cells, which in turn produce virus that infects additional surrounding cells. Over a period of days (the exact length of time depending on the particular virus), the initial infection thus gives rise through multiple rounds of infection to an area of infection, called a *plaque*. Photomicrographs of plaques are shown in Figure 2.5, and stained monolayers containing plaques are shown in Figure 2.6.

FIGURE 2.6. Plaque assay. Monolayers of the African green monkey kidney cell line BSC40 were infected with 0.5-mL portions of 10-fold serial dilutions of wild-type vaccinia virus or the temperature-sensitive vaccinia mutant, ts56, as indicated. Infected monolayers were overlaid with semisolid medium and incubated at 31°C or 40°C , the permissive and nonpermissive temperatures for ts56, in the presence of $45\ \mu\text{M}$ isatin- β -thiosemicarbazone (IBT) or in the absence of drug as indicated, for 1 week. Overlays were removed, and monolayers were stained with crystal violet. Wild-type vaccinia virus forms plaques at both 31°C and 40°C ; however, plaque formation is inhibited by IBT. Spontaneous IBT-resistant mutants in the wild-type virus stock are revealed as plaques forming at 10^{-3} , 10^{-4} , and 10^{-5} dilutions in the presence of IBT. ts56 carries a single-base missense mutation in the vaccinia gene *G2R*.⁸⁷ *G2R* is an essential gene that when completely inactivated renders virus dependent on IBT; hence, ts56 is not only temperature sensitive, forming plaques at 31°C but not at 40°C in the absence of IBT, but it is also IBT dependent at 40°C , forming plaques in the presence but not the absence of IBT. ts56 is slightly defective at 31°C ; it forms smaller than wild-type plaques and is IBT resistant, forming plaques both in the presence and absence of IBT, a phenotype intermediate between the wild-type IBT-sensitive phenotype and the null *G2R* mutant IBT-dependent phenotype. Wild-type, temperature-insensitive revertants present in the ts56 stock are revealed as plaques growing on the 10^{-3} plate at 40°C . Based on this assay, the titer of the wild-type stock is 2.0×10^9 pfu/mL, and the titer of the ts56 stock is 6.0×10^8 pfu/mL. IBT, isatin- β -thiosemicarbazone.

The plaque assay can be used to quantify virus in the following manner (see Fig. 2.6). A sample of virus of unknown concentration is serially diluted in an appropriate medium, and measured aliquots of each dilution are seeded onto confluent monolayers of cultured cells. Infected cells are overlaid with a semisolid nutrient medium usually consisting of growth medium and agar. The semisolid medium prevents formation of secondary plaques through diffusion of virus from the original site of infection to new sites, ensuring that each plaque that develops in the assay originated from a single infectious particle in the starting inoculum. After an appropriate period of incubation to allow development of plaques, the monolayer is stained so that the plaques can be visualized. The precise staining technique depends on the cytopathology; however, vital dyes such as neutral red are common. Neutral red is taken up by living cells but not by dead cells; thus, plaques become visible as clear areas on a red monolayer of cells. In cases where the virus cytopathology results in cell lysis or detachment of cells from the dish, plaques exist literally as holes in the monolayer, and a permanent record of the assay can be made by staining the monolayer with a general stain such as crystal violet, prepared in a fixative such as formalin. The goal of the assay is to identify a dilution of virus that yields 20 to 100 plaques on a single dish—that is, a number large enough to be statistically significant yet small enough such that individual plaques can be readily discerned and counted. Usually, a series of four to six 10-fold dilutions is tested, which are estimated to bracket the target dilution. Dishes inoculated with low dilutions of virus will contain only dead cells or too many plaques to count, whereas dishes inoculated with high dilutions of virus will contain very few, if any, plaques (see Fig. 2.6). Dishes containing an appropriate number of plaques are counted, and the concentration of infectious virus in the original sample can then be calculated taking into account the serial dilution. The resulting value is called a *titer* and is expressed in plaque-forming units per milliliter (pfu/mL) to emphasize specifically that only viruses capable of forming plaques have been quantified. Titers derived by serial dilution are unavoidably error prone, owing simply to the additive error inherent in multiple serial pipetting steps. Errors of up to 100% are normal; however, titers that approximate the real titer to within a factor of two are satisfactory for most purposes.

A critical benefit of the plaque assay is that it measures infectivity, although it is important to understand that infectivity does not necessarily correspond exactly to the number of virus particles in a preparation. In fact, for most animal viruses, only a fraction of the particles—as few as 1 in 10 to 1 in 10,000—may be infections as judged by comparison of a direct particle count, described later, with a plaque assay. This low *efficiency of plating*, or high particle to infectivity ratio, may have several causes. First, to determine a particle to infectivity ratio, virus must be purified to determine the concentration of physical particles and then subjected to plaque assay. If the purification itself damages particles, the particle to infectivity ratio will be increased. Second, some viruses produce empty particles, or particles that are for other reasons defective during infection, resulting in a high particle to infectivity ratio. Lastly, it is possible that not all infectious particles will form plaques in a given plaque assay. For example, infectious virus may require that cells exist in a specific metabolic state or in a specific stage of the cell cycle; thus, if not all cells in a culture are identical in this regard, only a fraction of the potentially

FIGURE 2.7. Focus assay. Monolayers of the NIH3T3 mouse fibroblast cell line were infected with Maloney murine sarcoma virus. **A, B:** Photomicrographs of uninfected cells (**A**) and a single virus-induced focus (**B**). **C:** Stained dishes of uninfected (**left**) and infected (**right**) cells. Foci are clearly visible as darker areas on the infected dish. (Courtesy of Dr. D. Blair.)

infectious virions may be able to successfully launch an infection and form a plaque.

In addition to its utility as a quantitative assay, the plaque assay also provides a way to detect genetic variants of a virus that possess altered growth properties, and it provides a very convenient method to clone genetically unique variants of a virus (see Fig. 2.6). Genetic variants are considered in detail in the Virus Genetics section; in brief, they may comprise viruses that plaque only under certain conditions of temperature or drug treatment, or form plaques of altered size or shape. Because each plaque results from infection with a single infectious virus particle, unique genetic variants of a virus can be cloned simply by picking plaques—that is, literally excising a small plug of semisolid medium and infected cells from a plaque using a Pasteur pipette.

THE FOCUS ASSAY

Some tumor viruses, most notably retroviruses, normally transform cells rather than killing them but can nevertheless be quantified by taking advantage of the transformation cytopathology.^{116,129} For example, retrovirus transformed cells may lose contact inhibition and therefore grow as foci, literally piles of transformed cells, on top of a contact-inhibited cell monolayer. Dense foci of transformed cells stain more darkly than cells in a monolayer and thus can be quantified on treatment of an infected monolayer with an appropriate stain. Otherwise, the focus assay is similar to the plaque assay in both technique and function. Photomicrographs of foci and stained monolayers containing foci are shown in Figure 2.7.

POCK FORMATION

As mentioned previously in the discussion of embryonated eggs, many viruses will cause focal lesions on the chorioallantoic membrane of eggs. While cumbersome, this assay can be used to quantify virus in a fashion similar to a plaque assay. The pock assay found utility before the adaptation of the plaque assay to animal virology, although now it has largely been replaced with other assays utilizing cultured cells and is used only for specialized purposes as noted in Figure 2.2.

THE ENDPOINT METHOD

Viruses that cannot be adapted to either a plaque or a focus assay but nevertheless cause some detectable pathology in cultured cells, embryonated eggs, or animals can be quantified using an endpoint method. Briefly, virus is serially diluted, and multiple replicate samples of each dilution are inoculated into an appropriate assay system. After a suitable incubation period, an absolute judgment is made as to whether or not an infection has taken place. The dilution series is constructed such that low dilutions show infection in all replicate inoculations, and high dilutions show infection in none of the inoculations, although some dilutions result in infection in some but not all inoculations. Statistical methods, described in more detail later, have been devised to calculate the dilution of virus that results in infection in 50% of replicate inoculations, and titers are expressed as the infectious dose 50 (ID_{50}). Assay systems are various and include, for example, observation of cytopathic effect in cultured cells, yielding tissue culture infective dose 50 ($TCID_{50}$); cytopathology or embryonic death in inoculated embryonated chicken eggs, yielding egg infective dose 50 (EID_{50}); or death of an experimental laboratory animal, yielding lethal dose 50 (LD_{50}). As with the plaque assay, the focus assay, and the pock assay, the endpoint method has the advantage of measuring infectivity; however, importantly, the unit of infectivity measured by the endpoint method may require more than one infectious particle. A sample determination of a $TCID_{50}$ is provided in the eBook.

Physical Assays

DIRECT PARTICLE COUNT

The concentration of virus particles in a sample of purified virus can be counted directly using an electron microscope.^{78,131} Briefly, a purified preparation of virus is mixed with a known concentration of microscopic marker particles such as latex beads, which can be easily distinguished from virus particles in the electron microscope. Samples of the solution containing virus and beads are then applied to an electron microscope grid and visualized following shadowing or staining. The volume of liquid applied to a given area of the grid can be determined by counting the beads. The virus particles in the same area can then be counted, resulting in an accurate determination of the concentration of virus particles in the original solution. An example of an electron microscopic count of vaccinia virus is shown in Figure 2.8. Given a solution of virus with a known concentration determined by microscopic particle count, the same solution can be subjected to any number of chemical or spectrophotometric analyses to yield a conversion from protein, nucleic acid, or simply absorbance at a fixed wavelength to a concentration of virus in particles per unit volume.

FIGURE 2.8. Direct electron microscopic particle count. An electron micrograph of a spray droplet containing 15 latex beads (spheres) and 14 vaccinia virus particles (slightly smaller brick-shaped particles). (Reprinted from Dumbell KR, Downie AW, Valentine RC. The ratio of the number of virus particles to infective titer of cowpox and vaccinia virus suspensions. *Virology* 4(3):467–482, © 1957 with permission from Elsevier.)

Thus, once a microscopic particle count has been performed, future quantitative assays of purified virus are greatly simplified. Importantly, the direct particle count does not distinguish infectious from noninfectious particles.

HEMAGGLUTINATION

As noted previously in the discussion of hemadsorption, many viruses express cell attachment proteins, which carry out their function wholly or in part by binding substituents such as sialic acid that are abundant on a wide variety of cell types, including erythrocytes. Because these cell attachment proteins decorate the surface of the virion, virions may bind directly to erythrocytes. Because both the virions and the erythrocytes contain multiple binding sites for each other, erythrocytes will agglutinate, or form a network of cells and virus, when mixed with virus particles in sufficiently high concentration. Agglutinated erythrocytes can be easily distinguished from cells that are not agglutinated, and thus hemagglutination can be used as a simple quantitative assay for the presence of a hemagglutinating virus.

In practice, a hemagglutination assay is carried out as follows (Fig. 2.9). Virus is serially diluted, mixed with a fixed concentration of erythrocytes, and the mixture is allowed to settle in a specially designed hemagglutination tray, containing wells

FIGURE 2.9. Hemagglutination assay. Seven different samples of influenza virus, numbered 1 through 7 at the **left**, were serially diluted as indicated at the **top**, mixed with chicken RBCs, and incubated on ice for 1 to 2 hours. Wells in the **bottom row** contain no virus. Agglutinated RBCs coat wells evenly, in contrast to nonagglutinated cells, which form a distinct button at the bottom of the well. The hemagglutination titer, shown at the **right** is the last dilution that shows complete hemagglutination activity. RBCs, red blood cells. (Courtesy of Drs. J. Talon and P. Palese.)

with rounded bottoms. Erythrocytes that are not agglutinated are free to roll to the bottom of the well, forming a dense, easily recognizable button, or cluster of cells. Erythrocytes that are agglutinated are not free to roll to the bottom of the well but instead evenly coat the bottom surface of the well to form what is called a *shield*. One hemagglutination unit is defined as the minimum amount of virus required to cause agglutination, and the titer of the virus solution, expressed as hemagglutination units per milliliter (HA units/mL), can be calculated taking into account the serial dilution. It is noteworthy that, such as with the direct particle count assay, the hemagglutination assay does not distinguish infectious from noninfectious particles. In addition, because it may require many particles to cause a detectable hemagglutination, one HA unit may represent many physical particles.

Quantitative Considerations in Virus Assay, Cultivation, and Experimentation

Dose Response in Plaque and Focus Assays

With few exceptions, the number of infectious units observed on a given plate in a plaque assay is a linear function of the dilution of the virus; thus, the development of plaques follows single-hit kinetics, proving that each plaque results from infection with a single virus particle. Exceptions include the murine sarcoma viruses, assayed in a focus assay, which require co-infection with both a defective transforming virus and a nondefective helper virus, in which case the number of foci observed relative to the dilution used follows two-hit kinetics.⁴⁶

Comparison of Quantitative Assays

As noted in the previous individual descriptions, the various quantitative assays of viruses measure different physical and biological properties, and a one-to-one correlation between assays cannot be assumed. Table 2.3 summarizes the titers of an influenza virus preparation as measured by several different

assays and thus provides an example the magnitude of differences that might be expected in the various assays. Hence, relative to a direct particle count, the efficiency of virus detection in the influenza sample shown in Table 2.3 is 10^{-1} as assayed in eggs, 10^{-2} as assayed in a plaque assay, and 10^{-7} as assayed in a hemagglutination assay. As indicated in the foregoing discussion, some differences result from different properties being measured (e.g., physical particles versus infectivity), and some differences result from differences in the sensitivity of the assay (e.g., direct particle count versus assay of particles by hemagglutination).

Multiplicity of Infection

Multiplicity of infection, often abbreviated “moi,” measures the average amount of virus added per cell in an infection. Multiplicity of infection can be expressed using any quantitative measure of virus titer—for example, particles/cell, HA units/cell, TCID₅₀/cell, or pfu/cell. Because the efficiency of plating varies depending on the method of quantitation used, some knowledge of the infectivity of the sample or the efficiency

TABLE 2.3 Comparison of Quantitative Assay Efficiency

Method	Amount (per mL)
Direct electron microscope count	10^{10} EM particles
Quantal infectivity assay in eggs	10^9 egg ID ₅₀
Quantal infectivity assay by plaque formation	10^8 pfu
Hemagglutination assay	10^3 HA units

EM, electron microscopy; ID₅₀, infective dose 50; pfu, plaque-forming unit; HA, hemagglutination assay.

of plating is required to correctly anticipate the consequences of the use of a particular moi. The multiplicity of infection used in different protocols can have a profound outcome on the procedure. For example, some viruses, if serially passaged at a moi of greater than 1 infectious unit/cell, will accumulate spontaneously deleted defective particles that are maintained during passage by the presence of complementing wild-type helper virus.¹³⁰ Passage of the same virus at very low moi (e.g., 0.01 infectious units/cell) discourages the accumulation of defective particles because few cells will be co-infected with an infectious and a defective particle, and defective particles cannot replicate in the absence of a wild-type helper. Conversely, most metabolic labeling experiments are done at a high moi (e.g., 10 infectious units/cell) to ensure that all cells in the culture are infected and that the infection is as synchronous as possible. For such experiments, use of too low a moi may result in an apparently asynchronous infection and a high background owing to the presence of uninfected cells in the culture.

The Poisson distribution can be used to predict the fraction of cells in a population infected with a given number of particles at different multiplicities of infection. As applied to virus infections, the Poisson distribution can be written as:

$$P(k) = e^{-m} m^k / k!,$$

where $P(k)$ equals the probability that any cell is infected with k particles, m equals moi, and k equals the number of particles in a given cell.

To determine the fraction of uninfected cells in any experiment—that is, when $k = 0$ —the equation simplifies to:

$$P(0) = e^{-m}$$

For practical purposes, solution of this equation for given values of m and k (other than 0) is most easily accomplished using published tables.¹⁴² Sample solutions are shown in Table 2.4 for commonly used multiplicities of infection. Inspection of this table and consideration of the error inherent in any virus titration involving a serial dilution leads to some significant practical guides in experimental design. Note first that in a culture infected at a moi of 1 pfu/cell, 37% of cells remain

uninfected—an unacceptably high number for an experiment designed to measure a single round of synchronous infection. A moi of at least 3 is required to infect 95% of the cells in culture. Given that titers can easily be inaccurate by a factor of two, the use of a calculated moi of 10 ensures that 99% of the cells in a culture will be synchronously infected even if the measured titer is twofold higher than the actual titer.

One-Step Growth Experiment

A classic experiment developed initially for bacteriophage²⁹ and still frequently used to determine the essential growth properties of a virus is the one-step growth experiment. The goal of this experiment is to measure the time course of virus replication and the yield of virus per cell during a single round of infection. The experiment is carried out as follows. Several dishes containing confluent monolayers of an appropriate cultured cell are infected simultaneously with virus at a high moi (e.g., 10 pfu/cell). After an adsorption period, monolayers are washed to remove unabsorbed virus and then incubated in culture medium. At various times after infection, virus from individual dishes is harvested, and at the completion of the experiment, the virus titer in samples representing each time point is determined. The virus yield at each point can be converted to pfu/cell (also called *burst size*) by dividing the total amount of virus present in the sample by the number of cells originally infected in the sample.

The results from one example of a one-step growth experiment, in this case comparing growth of wild-type vaccinia virus and a temperature-sensitive mutant at permissive and nonpermissive temperatures, are shown in e-Figure 2.1. Several features of the growth curve are noteworthy. First, during the first several hours of the wild-type infection or the $\Delta 56$ infection at the permissive temperature, the titer in the cultures decreases and then increases. This dip in the growth curve is called *eclipse* and results from the fact that early during the experiment, virus attached to the cell surface but not uncoated remains infectious; however, infectivity is lost following uncoating during the first few hours of infection, and infectivity is recovered only after new virus is produced. The infection then enters a rapid growth phase, followed by a plateau. The plateau results from the fact that all infected cells have reached the maximum yield of virus, or have died or lysed, depending on the type of virus infection. The time interval from infection to plateau represents the time required for a single cycle of growth, and the yield of virus at plateau shows the amount of virus produced per cell. The experiment in e-Figure 2.1 demonstrates the utility of the one-step growth experiment. As judged by this experiment, wild-type virus grows with identical kinetics and to the identical yields at both 31°C and 40°C, which are permissive and nonpermissive temperatures for the temperature-sensitive mutant, respectively. The temperature-sensitive mutant, $\Delta 56$,⁸⁷ grows more slowly than wild-type virus at 31°C, indicating some defective character even at the permissive temperature, although at plateau the yields of mutant virus at 31°C are equivalent to wild-type virus. The experiment demonstrates conclusively that the mutant does not grow at all at the nonpermissive temperature of 40°C.

Multiplicity of infection is a critical factor in the design of a virus growth experiment. A true one-step growth experiment can only be done at high moi. If the moi is too low and a large fraction of cells are left uninfected, then virus produced during

TABLE 2.4 The Poisson Distribution: Values of $P(k)$ for Various Values of m and k

moi, multiplicity of infection.

the first round of infection will replicate on previously uninfected cells, and thus multiple rounds of infection rather than one round will be measured. A growth experiment done at low *moi* has utility in that it measures both growth and spread of a virus in culture; however, the time from infection to plateau does not accurately reflect the time required for a single cycle of infection. It is also noteworthy that some mutant phenotypes are multiplicity dependent.⁶

VIRUS GENETICS

Viruses are subject to the same genetic principles at work in other living systems, namely mutation, selection, complementation, and recombination. Genetics impacts all aspects of virology, including the natural evolution of viruses, clinical management of virus infections, and experimental virology. For example, antigenic variation, which is a direct result of mutation and selection, plays a prominent role in the epidemiology of influenza virus and human immunodeficiency virus (HIV) in the human population, and mutation to drug resistance offers a significant challenge to the clinical management of virus infections with antiviral drugs. This section deals primarily with the application of experimental genetic techniques to basic virology.

The ultimate goal of experimental virology is to understand completely the functional organization of a virus genome. In a modern context, this means determination of the structure of a virus genome at the nucleotide sequence level, coupled with isolation of mutational variants of the virus altered in each gene or control sequence, followed by analysis of the effects of each mutation on the replication and/or pathogenesis of the virus. Thus, genetic analysis of viruses is of fundamental importance to experimental virology.

Before the advent of modern nucleic acid technology—that is, during a *classical* period of *forward* genetics—genetic analysis of viruses consisted of the random, brute force isolation of large numbers of individual virus mutants, followed first by complementation analysis to determine groupings of individual mutants into genes, then recombination analysis to determine the physical order of genes on the virus genome, and finally the phenotypic analysis of mutants to determine gene function. This approach, pioneered in the 1940s through the 1960s in elegant studies of several bacteriophage, notably lambda, T4, and T7 (Chapter 75), was the primary method for identifying, mapping, and characterizing virus genes. The application of cell culture techniques to animal virology opened the door to classical genetic analysis of animal viruses, resulting in a flurry of activity in the 1950s through the 1970s, during which time hundreds of mutants were isolated and analyzed in prototypical members of most of the major animal virus families.³⁸ Modern nucleic acid technology introduced in the 1970s brought with it a variety of techniques for physical mapping of genomes and mutants, including restriction enzyme mapping, marker rescue, and DNA sequence analysis, which together replaced recombination analysis as an analytic tool. Mutants and techniques from the classical period continue to be of enormous utility today; however, recombinant DNA technology has brought with it *reverse* genetics, in which the structure of the genome is determined first using entirely physical methods, then the function of individual genetic ele-

ments is determined by analyzing mutants constructed in a highly targeted fashion.

The genetic approach to experimental virology, or any field of biology for that matter, has the profound advantage of asking of the organism under study only the most basic question—What genes do you need to survive, and why do you need them?—without imposing any further bias or assumptions on the system. Happily, organisms often respond with surprises that the most ingenious biochemist or molecular biologist would never have imagined. What follows is a summary of the critical elements of both the classical and modern approaches to virus genetics as applied to experimental virology.

Mutants

Wild-type Virus

It is important to understand that in the context of experimental virus genetics, a virus designated as *wild-type* can differ significantly from the virus that actually occurs in nature. For example, virus genetics often relies heavily on growth and assay of viruses in cell culture, and as noted previously, natural isolates of viruses may undergo significant genetic change during adaptation to cell culture. In addition, viruses to be designated as wild-type should be plaque purified before initiating a genetic study to ensure a unique genetic background for mutational analysis. Lastly, viruses may be specifically adapted for use in genetic analysis—for example, by passage under conditions that are to be restrictive for conditionally lethal mutants so that the analysis can be initiated with a preparation free from spontaneous mutants.

Fundamental Genetic Concepts

Concepts fundamental to genetic analysis of other organisms apply to genetic analysis of viruses, and a clear understanding of these concepts is essential to understanding virus genetics. The most important of these concepts, including distinctions between genotype and phenotype, a selection and a screen, and essential versus nonessential genes, are briefly summarized next.

GENOTYPE AND PHENOTYPE

Genotype refers to the actual genetic change from wild-type in a particular virus mutant, whereas *phenotype* refers to the measurable manifestation of that change in a given assay system. This distinction is emphasized by the fact that a single genotype may express different phenotypes depending on the assay applied. Thus, for example, the same missense mutation in a virus gene may cause temperature sensitivity in one cell line but not another, or a deletion in another virus gene may have no effect on the replication of virus in culture but may alter virulence in an animal model.

SELECTION AND SCREEN

Selection and screen refer to two fundamentally different methods of identifying individual virus variants contained in a mixed population of viruses. *Selection* implies that a condition exists where only the desired virus will grow, and growth of unwanted viruses is suppressed. Thus, a drug-resistant virus can be identified by plating a mixture of wild-type, drug-sensitive, and mutant, drug-resistant viruses together on the same cell monolayer in the presence of the inhibitory drug, thereby selecting for drug-resistant viruses that grow,

and selecting against wild-type viruses that do not grow (see Fig. 2.6). A *screen* implies that both the desired virus variant and one or several other unwanted virus types grow under a given condition, such that many viruses must be analyzed individually to identify the desired variant. For example, in searching for a temperature-sensitive mutant (i.e., a virus whose growth is inhibited relative to wild-type virus at an elevated temperature), no condition exists under which the mutant alone will grow. Therefore, virus must be plated at a low temperature where both wild-type and mutant virus will grow, and plaques tested individually for temperature sensitivity. Sometimes a screen can be streamlined by introducing a phenotypic marker into the variant of choice. For example, a knockout virus might be constructed by inserting the β -galactosidase gene into the virus gene to be inactivated. In the presence of an appropriate chromophoric substrate, viruses containing the insertional knockout produce blue-colored plaques and can therefore be distinguished from unmodified viruses, which form clear plaques, growing on the same plate.¹³⁹ This latter example is still a screen, because both wild-type and mutant viruses grow under the conditions used; however, the screen is simplified because mutant viruses can be readily identified by their color, obviating the need to pick and test individual plaques. Selections have considerable advantages over screens but are not always possible.

ESSENTIAL AND NONESSENTIAL

The terms *essential* and *nonessential* describe phenotypes, specifically whether a given gene is required for growth under a specific condition. Most viruses are finely tuned through selection to fit a specific niche. Not all viral genes are absolutely required for virus replication in that niche; some may simply confer a subtle selective advantage. Furthermore, if the niche is changed—such as from a natural animal host to a cell line in a laboratory—some genes that may have been essential for productive infection in the animal may not be required for replication in cell culture. Genes that are required for growth under a specific condition are termed *essential*, and those that are not required are termed *nonessential*. Because as a phenotype essentiality may be a function of the specific test conditions, the test conditions need to be specified in describing the mutation. As an example, the herpesvirus thymidine kinase gene is nonessential for virus replication in cell culture. Genes that are either essential or nonessential under a given condition present unique characteristics for analysis. Thus, mutants in nonessential genes may be easy to isolate because the gene can be deleted, although the function of the gene may be difficult to determine because, by definition, nonessential genes have no phenotype. Conversely, genes that are essential can be used to study gene function by characterizing the precise replication defect caused by a mutation in the gene; however, acquiring the appropriate mutant is confounded by the necessity for identifying a condition that will permit growth of the virus for study.

Mutation

SPONTANEOUS MUTATION

Spontaneous mutation rates in viruses are measured by fluctuation analysis,⁶⁰ a technique pioneered by Luria and Delbrück⁷⁷ for analysis of mutation in bacteria, and later adapted to viruses

by Luria.⁷⁵ Fluctuation analysis consists of measuring the proportion of spontaneous mutants with a particular phenotype in many replicate cultures of virus and applying the Poisson distribution to these data to calculate a mutation rate. Importantly, because spontaneous mutations occur at random and may occur only rarely, the raw data in a fluctuation analysis displays enormous scatter, with some cultures containing a high proportion of mutants and some containing no mutants. Thus, from a practical perspective, although the proportion of mutants in a single culture of virus may reflect the mutation rate, it does not necessarily provide an accurate measure of mutation rate.

Both DNA and RNA viruses undergo spontaneous mutation; however, the spontaneous mutation rate in RNA viruses is usually much higher than in DNA viruses. In general, the mutation rate at a specific site in different DNA viruses ranges from 10^{-8} to 10^{-11} per replication, whereas in RNA viruses it is at least hundred-fold higher, between 10^{-3} and 10^{-6} per replication. The difference in mutation rate observed between RNA and DNA viruses is thought to result primarily from differences in the replication enzymes. Specifically, the DNA-dependent DNA polymerases used by DNA viruses contain a proofreading function, whereas the reverse transcriptases used by retroviruses and RNA-dependent RNA polymerases used by RNA viruses lack a proofreading function. The difference in spontaneous mutation rate has profound consequences for both the biology of the viruses and for laboratory genetic analysis of viruses. Specifically, RNA viruses exist in nature as *quasispecies*²⁵—that is, populations of virus variants in relative equilibrium with the environment but capable of swift adaptation owing to a high spontaneous mutation rate (Chapter 11). Conversely, DNA viruses are genetically more stable but less adaptable. In the laboratory, the high mutation rate in RNA viruses presents difficulties in routine genetic analysis because mutants easily revert to wild-type virus that can outgrow the mutant virus.

It is noteworthy that whereas the actual mutation rate at a single locus is probably relatively constant for a given virus, the apparent mutation rate to a given phenotype depends on the nature of the mutation(s), which can give rise to that phenotype. For example, spontaneous mutation to bromodeoxyuridine (BrdU) resistance in vaccinia virus may occur at least 10 to 100 times more frequently than spontaneous reversions of temperature-sensitive mutations to a wild-type, temperature-insensitive phenotype. In the case of BrdU resistance, any mutation that inactivates the thymidine kinase causes resistance to BrdU, and thus there are literally hundreds of different ways in which spontaneous mutation can give rise to BrdU resistance. By contrast, a temperature-sensitive mutation is usually a single-base missense mutation, in which may exist only one possible mutational event that could cause reversion to the wild-type phenotype; thus, the apparent spontaneous mutation rate for the revertant phenotype is lower than the apparent spontaneous mutation rate to the BrdU-resistant phenotype. From a practical perspective, the apparent spontaneous mutation rate for specific selectable phenotypes may be sufficiently high such that induction of mutants is unnecessary for their isolation. Note, for example, that the wild-type vaccinia virus culture titrated in Figure 2.6 contains numerous spontaneous isatin- β -thiosemicarbazone (IBT)-resistant viruses that could easily be plaque purified

from assays done in the presence of IBT. However, for most mutants (e.g., temperature-sensitive mutants), where the desired mutational events are rare and a screen must be used rather than a selection, induced mutation is required for efficient isolation of mutants.

INDUCED MUTATION

Under most circumstances, the incidence of spontaneous mutations is low enough so that induction of mutation is a practical prerequisite for isolation of virus mutants. It is usually desirable to induce limited, normally single-base changes, and for this purpose, chemical mutagens are most appropriate. Commonly used chemical mutagens are of two types: *in vitro* mutagens and *in vivo* mutagens.²⁶ *In vitro* mutagens work by chemically altering nucleic acid and can be applied by treating virions in the absence of replication. Examples of *in vitro* mutagens include hydroxylamine, nitrous acid, and alkylating agents, which through chemical modification of specific bases cause mispairing leading to missense mutations. *In vivo* chemical mutagens comprise compounds such as nucleoside analogs that must be incorporated during viral replication and thus must be applied to an infected cell. One of the most effective mutagens is the alkylating agent nitrosoguanidine, which although is capable of alkylating nucleic acid *in vitro* is most effective when used *in vivo*, where it works by alkylating guanine residues at the replication fork, ultimately causing mispairing.

The effectiveness of a mutagenesis is often assayed by observing the killing effect of the mutagen on the virus, the assumption being that many mutational events will be lethal and thus an effective mutagenesis will decrease a virus titer relative to an untreated control. However, killing does not always correlate precisely with mutagenesis, especially with an *in vitro* mutagen that can damage virion structure without necessarily causing mutation. An alternative method for assessing mutagenesis is to monitor an increase in the mutation frequency to a selectable phenotype where possible. For example, in vaccinia virus, mutagenesis causes a dose-dependent increase in resistance to phosphonoacetic acid, a drug that prevents poxvirus replication by inhibiting the viral DNA polymerase.¹² In summary, the use of mutagens can increase the mutation frequency several hundred-fold, such that desired mutants may comprise as much as 0.5% of the total virus population.

DOUBLE MUTANTS AND SIBLINGS

The existence of *double mutants* and *siblings* can theoretically complicate genetic analysis of a virus. A double (or multiple) mutant is defined as a virus that contains more than one mutation contributing to a phenotype. Theoretically, because the probability that a double mutant will be created increases as the dose of a mutagen is increased, there is a practical limit to the amount of induced mutation that is desirable. Double mutants are usually revealed as mutants that are noncomplementing with more than one mutant or are impossible to map by recombination or physical methods. Siblings result from replication of mutant virus either through amplification of a mutagenized stock or during an *in vivo* mutagenesis. The only completely reliable method to avoid isolation of sibling mutants is to isolate each mutant from an independently plaque-purified stock of wild-type virus.

Mutant Genotypes

There exist two basic categories of mutation: base substitution and deletion/insertion mutations. Both mutation types can occur with consequence in either a protein coding sequence or in a control sequence, such as a transcriptional promoter, a replication origin, or a packaging sequence. *Base substitution* mutations consist of the precise replacement of one nucleotide with a different nucleotide in a nucleic acid sequence. In coding sequences, base substitution mutations can be silent, causing no change in amino acid sequence of a protein; they can be missense, causing replacement of the wild-type amino acid with a different residue; or they can be nonsense, causing premature translation termination during protein synthesis. *Deletion and insertion* mutations comprise deletion or insertion of one or more nucleotides in a nucleic acid sequence. In a coding sequence, deletion or insertion of multiples of three nucleotides can result in precise deletion or insertion of one or more amino acids in a protein sequence. In a coding sequence, deletions or insertions that do not involve multiples of three nucleotides result in a shift in the translational reading frame, which almost invariably results in premature termination at some distance downstream of the mutation. In general, nonsense mutations, frameshift mutations, or large in-frame insertions or deletions are expected to inactivate a gene, whereas missense mutations may cause inactivation or much more subtle phenotypes such as drug resistance or temperature sensitivity.

Mutant Phenotypes

In the context of experimental virology where the goal is to understand the function of individual virus genes, the most useful mutants are those that inhibit virus replication by inactivating a virus gene. The nonproductive infections with these lethal mutants can be studied in detail to determine the precise aspect of virus replication that has been affected, thus providing information about the normal function of the affected gene. However, one must be able to grow the mutant to conduct experiments. Thus, a condition must be found where the mutation in question is not lethal—hence, the general class of mutant phenotypes, *conditional lethal*. Conditional lethal mutants comprise by far the largest and most useful class of mutant phenotypes, consisting of host-range, nonsense, temperature-sensitive, and drug-dependent phenotypes, described individually in the next section. Two additional classes of mutant phenotypes—resistance and plaque morphology—have very specific application to genetic analysis of viruses and are also described.

HOST RANGE

A host-range virus mutant is broadly defined as a mutant that grows on one cell type and not on another, in contrast to wild-type virus, which grows on both cell types. Two general subcategories of host-range mutants exist: natural and engineered. *Natural* host-range virus mutants are relatively rare, primarily because they must be identified by brute force screen or serendipity, in many cases in the absence of a viable rationale for the targeted host range. The existence of a host-range phenotype implies that a specific virus–host interaction is compromised, which also implies that for any specific host-range phenotype, only one or a limited number of virus genes will be targeted. A classic example of a natural host-range mutant would be the host range-transformation (hr-t) mutants of mouse polyoma

virus, which affect both small and middle T antigens and grow on primary mouse cells but not continuous mouse 3T3 cell lines.³ *Engineered* host-range mutants are constructed by deleting an essential gene of interest in the virus while at the same time creating a cell line that expresses the gene. The engineered cell line provides a permissive host for growth of the mutant virus because it complements the missing virus function, whereas the normal host lacking the gene of interest provides a nonpermissive host for study of the phenotype of the virus. This technology has been useful for study of a variety of viruses, notably adenovirus and herpes simplex virus, where it has facilitated study of several essential virus genes.^{21,61}

NONSENSE MUTANTS

Nonsense mutants contain a premature translation termination mutation in the coding region of the mutant gene. They are formally a specific class of conditionally lethal, host-range mutants. Specifically, the permissive host is one that expresses a transfer RNA (tRNA) containing an anticodon mutation that results in insertion of an amino acid in response to a nonsense codon, thus restoring synthesis of a full-length polypeptide and suppressing the effects of the virus nonsense mutation. The nonpermissive host is a normal cell in which a truncated, nonfunctional polypeptide is made. In practice, most nonsense mutants in existence have been isolated by random mutagenesis followed by a brute force screen for host range. Nonsense mutants have three distinct advantages for the conduct of virus genetics: (a) mutants can be isolated in virtually any essential virus gene using one set of permissive and nonpermissive hosts and one set of techniques; (b) the mutations result in synthesis of a truncated polypeptide, thereby facilitating identification of the affected gene; and (c) virus mutants can be engineered relatively easily because the exact sequence of the desired mutation is predictable. Nonsense mutants have provided the single most powerful genetic tool in the study of bacteriophage, where efficient, viable nonsense suppressing bacteria are readily available. Unfortunately, attempts to isolate nonsense-suppressing mammalian cells have met with only limited success, probably because the nonsense-suppressing tRNAs are lethal in the eukaryotic host.¹¹⁰

TEMPERATURE SENSITIVITY

Temperature sensitivity is a type of conditional lethality in which mutants can grow at a low temperature but not a high temperature, in contrast to wild-type virus, which grows at both temperatures (see Fig. 2.6). Genotypically, temperature-sensitive mutations result usually from relatively subtle single amino acid substitutions that render the target protein unstable and hence nonfunctional at an elevated or nonpermissive temperature while leaving the protein stable and functional at a low, permissive temperature. In practice, temperature-sensitive mutants are usually isolated by random mutagenesis followed by brute force screening for growth at two temperatures. Screening can be streamlined by a plaque enlargement technique in which mutagenized virus is first plated at a permissive temperature, then stained and shifted to a nonpermissive temperature after marking the size of plaques, to screen for plaques that do not increase in size at the nonpermissive temperature.¹¹² Replica plating techniques that permit relatively straightforward screening of thousands of mutant candidates in yeast and bacteria have not been successfully adapted to virology; thus, a screen

for temperature sensitivity, even when streamlined with plaque enlargement, ultimately depends on the laborious but reliable process of picking and testing individual plaques. Temperature-sensitive mutants have the profound advantage of theoretically accessing any essential virus gene using a single set of protocols. Temperature-sensitive mutants have proved enormously useful in all branches of virology but have been particularly useful for the study of animal viruses, where nonsense suppression has not been a viable option. Cold-sensitive mutants (i.e., mutants that grow at a high but not a low temperature) comprise a relatively rare but nevertheless useful alternate type of temperature-sensitive mutants.

Temperature-sensitive mutants can actually be divided into two subclasses: thermolabile and temperature sensitive for synthesis (tss) mutants.¹⁴⁰ *Thermolabile mutants* are those in which the gene product can be inactivated following synthesis by a shift from the permissive to the nonpermissive temperature. *Ts* mutants display gene dysfunction only if the infection is held at the nonpermissive temperature during synthesis of the mutant gene product; if the gene product is made at the permissive temperature, it cannot be inactivated by raising the temperature. Clearly, the two mutant types can be distinguished by performing appropriate temperature shift experiments. Thermolability obviously implies that a protein preformed at the permissive temperature is directly destabilized by raising the temperature. Tss mutations commonly involve multisubunit structures or complex organelles, where theoretically the quaternary structure of a complex formed correctly at the permissive temperature stabilizes the mutant protein, making the mutation resistant to temperature shift. If a tss mutant protein is synthesized at the nonpermissive temperature, it may be degraded before assembly or may not assemble properly because of misfolding. For most purposes, the thermolabile and tss mutant types are equally useful.

DRUG RESISTANCE AND DEPENDENCE

Several antiviral compounds have now been identified, and virus mutants that are resistant to or depend on these compounds have found utility in genetic analysis of viruses. A few compounds have been identified that target similar enzymes in different viruses, including phosphonoacetic acid, which inhibits DNA polymerases^{50,114} and BrdU, which targets thymidine kinases.^{27,119} More often, however, antiviral drugs are highly specific for a gene product of one particular virus—for example, guanidine, which targets the polio 2C NTPase^{98,99}; acyclovir, which targets the herpes simplex virus thymidine kinase and DNA polymerase^{9,109}; amantadine, which targets the influenza virus M2 virion integral membrane ion channel protein⁴⁹; or isatin- β -thiosemicarbazone, which is highly specific for poxviruses and targets at least two genes involved in viral transcription.^{11,17,87} The most useful drugs are those that inhibit wild-type virus growth in a plaque assay without killing cells in a monolayer, such that resistant or dependent viruses can be selected by virtue of their ability to form plaques on a drug-treated monolayer. Examples of both drug resistance and drug dependence are shown in Figure 2.6.

Drug-resistant or drug-dependent virus mutants have two general uses in virus genetics. First, they can be useful in identifying the target or mechanism of action of an antiviral drug. For example, studies of influenza virus mutants resistant to amantadine were of importance in characterizing both the M2

gene and the mechanism of action of amantadine.¹⁰⁰ Second, resistant or dependent mutants provide selectable markers for use in recombination mapping, for the assessment of specific genetic protocols, or for selection of recombinant viruses in reverse genetic protocols. For example, guanidine resistance has been used as a marker for use in three-factor crosses in recombination mapping of poliovirus temperature-sensitive mutants¹⁶; phosphonoacetic acid resistance and isatin- β -thiosemicarbazone dependence has been used in vaccinia virus to assess the efficiency of marker rescue protocols^{31,47}; and acyclovir resistance and BrdU resistance, resulting from mutation of the herpesvirus or poxvirus thymidine kinase genes, has been used in both herpesviruses and in poxviruses to select for insertion of engineered genes into the viral genome.^{10,80,94}

PLAQUE MORPHOLOGY

Plaque morphology mutants are those in which the appearance of mutant plaques is readily distinguishable from wild-type plaques. Most commonly, the morphological distinction is plaque size (i.e., mutant plaques may be larger or smaller than wild-type plaques); however, other morphological distinctions are possible, such as formation of clear versus turbid bacteriophage plaques. Most plaque morphology mutants affect very specific virus functions, which in turn affect the virus–host relationship in a fashion that impacts on the appearance of a plaque. Notable examples from bacteriophage research include clear plaque mutants of bacteriophage lambda and rapid lysis mutants of the T-even bacteriophage. Wild-type lambda forms turbid plaques because some percentage of cells are lysogenized and thus survive the infection, leaving intact bacteria within a plaque. Clear mutants of lambda typically affect the lambda repressor such that lysogeny is prevented and all infected bacteria lyse, resulting in a clear plaque.⁶³ Wild-type T-even phages produce small plaques with a turbid halo because only a fraction of infected bacteria lyse during a normal infection, a phenomenon called *lysis inhibition*. Rapid lysis mutants, which affect a phage membrane protein, do not display lysis inhibition and as a result form large, clear plaques.⁵³ Examples from animal virus research include large plaque mutants of adenovirus and syncytial mutants of herpes simplex virus. The large plaque phenotype in adenovirus results from faster than normal release of virus from infected cells.⁶⁸ Syncytial mutants of herpesvirus express altered virus surface glycoproteins and result in fusion of infected cells, whereas wild-type virus causes cells to round and clump without significant fusion. Thus, syncytial mutants form large plaques readily distinguishable from the smaller dense foci caused by wild-type virus.¹⁰⁷ All of these specific plaque morphology mutants have value either in the study of the actual functions affected or as specific phenotypic markers for use in recombination studies, where they can be used in the same fashion as drug resistance markers, described previously.

In addition to the existence of specific plaque morphology loci in several viruses, it is noteworthy that any mutation that affects virus yield or growth rate may result in production of a smaller than wild-type plaque, which can be useful in genetic experiments. Thus, many temperature-sensitive mutants form smaller than wild-type plaques even at the permissive temperature because the mutant gene may not be fully functional even under permissive conditions, and this property is often useful in mutant isolation or for distinguishing wild-type from mutant virus in plaque assays involving several virus variants. Note,

for example, in Figure 2.6 that the vaccinia virus temperature-sensitive mutant *ts56* forms smaller than wild-type plaques at the permissive temperature of 31°C. Lastly, intragenic or extragenic suppressors of conditional lethal virus mutants may grow poorly relative to wild-type virus and form small plaques as a result, facilitating their isolation from a mixture containing true wild-type revertant viruses.¹⁴

NEUTRALIZATION ESCAPE

Neutralization escape mutants are a specific class of mutants selected as variant viruses that form plaques in the presence of neutralizing antibodies. Such mutants affect the structure or modification of viral surface proteins and have been of value in studies of virus structure, antigenic variation, and virus–cell interactions.^{43,55}

Reversion

Reversion may be defined as mutation that results in a change from a mutant genotype to the original wild-type genotype. Accordingly, revertants in a stock of mutant virus are revealed as viruses that have acquired a wild-type phenotype. For example, Figure 2.6 shows that when the vaccinia virus temperature-sensitive mutant *ts56* is plated at the nonpermissive temperature, plaques with wild-type morphology, probably revertants, are detectable at low dilutions of virus. Spontaneous reversion of missense mutations probably results from misincorporation during replication, because the reversion frequency of different viruses often reflects the error rate of the replication enzyme. Spontaneous reversion of significant deletion mutations occurs rarely, if at all, because reversion would require replacement of missing nucleotides with the correct sequence. Reversion impacts on viral genetics in two ways. First, in any genetic experiment involving mixed infections with two genetically different viruses, wild-type viruses can arise either through reversion or recombination; in most cases, it is important to be able to distinguish between these two processes. This is discussed in more detail in the later sections describing complementation and recombination. Second, as described earlier in the description of spontaneous mutation, if the spontaneous reversion rate is extremely high, revertants can easily come to dominate a mutant virus stock, thus obscuring the mutant phenotype and causing serious difficulties in both genetic and biochemical analysis of mutants.

Leakiness

Not all conditionally lethal mutants are completely defective in replication under nonpermissive conditions, and leakiness is a quantitative measure of the ability of a mutant virus to grow under nonpermissive conditions. Leakiness can be quantified with a one-step growth experiment. To quantify leakiness of a temperature-sensitive mutant, for example, cells are infected at a high moi with wild-type or mutant virus, infected cells are incubated at either permissive or nonpermissive temperatures, and maximum virus yields are then determined by plaque titration under permissive conditions so that the growth of mutant and wild-type virus can be quantitatively compared. Ideally, for wild-type virus, the ratio of the yield for infections done at the nonpermissive temperature relative to the permissive temperature should be one—that is, the virus should grow equally well at both temperatures. For mutant viruses, the ratio of the

yield for infections done at the nonpermissive temperature relative to the permissive temperature may range from less than 10% to as much as 100%, even for mutants that are clearly defective in plaque formation under nonpermissive conditions. Mutants that are *tight*—or grow poorly under nonpermissive conditions—are desirable for phenotypic characterization relative to leaky mutants, because leaky mutants will logically display considerable wild-type phenotypic behavior. Special cases exist where extreme leakiness is an expected and desirable trait. Specifically, virus mutants that are wild-type for replication and production of infectious virions but defective in cell-to-cell spread have a phenotype characterized by defective plaque formation, which requires spread, but 100% leakiness, which does not require spread if assayed in a high moi one-step growth protocol.⁵

Genetic Analysis of Mutants

Complementation

Complementation analysis provides a general method for determining whether two different virus mutants affect the same or different genes. The quantitative test to determine complementation is a two-step procedure in which co-infections are first done to induce an interaction between two mutants, and the results of those infections are quantitatively assessed by plaque titration. The test compares the ability of two mutants to grow in mixed relative to single infections done under nonpermissive conditions. Specifically, cells are first infected with two different virus mutants at high moi so that all cells are co-infected with both mutants, and infected cells are incubated under nonpermissive conditions where neither mutant alone can replicate, for an interval sufficient to achieve maximum virus yield. Single high moi infections under nonpermissive conditions are performed as controls. Virus is then harvested, yields are quantified by plaque titration under both permissive and nonpermissive conditions, and a complementation index (CI) is calculated according to the following formula:

$$\frac{\text{yield}(A+B)_p - \text{yield}(A+B)_{np}}{\text{yield}(A)_p + \text{yield}(B)_p} = \text{CI},$$

where A and B represent individual virus mutants, and the subscripts p and np represent the conditions, either permissive or nonpermissive, under which the virus yields were plaque titrated. Because both mutant and wild-type viruses will be counted in plaque titrations done at the permissive temperature, the first term in the numerator, $\text{yield}(A+B)_p$, measures the yield of all viruses, both mutant and wild-type, from the initial high moi mixed infections done under nonpermissive conditions. The second term in the numerator, $\text{yield}(A+B)_{np}$, measures the yield of wild-type viruses, mostly recombinants, from the high moi mixed infections done under nonpermissive conditions, because only wild-type viruses will be counted in plaque titrations done at the nonpermissive temperature. Subtraction of the wild-type viruses from the total viruses leaves a count of only the mutant viruses in the numerator. The denominator measures the ability of each of the mutants to grow in single high moi infections done initially under nonpermissive conditions. If the two mutants, A and B, are in different virus genes, then in the mixed infection done under nonpermissive

conditions, mutant A can contribute wild-type B gene product and mutant B can contribute wild-type A gene product. Thus, the mutants can help or complement each other, resulting in a high yield of mutant virus in the mixed infection compared to the single infections, and a CI significantly greater than one. If the two mutants, A and B, affect the same gene, then the wild-type gene product will be lacking in the mixed infection. In this case, the yield from the mixed infection will be equivalent to the yield from the single infections, and the CI should not exceed one. In practice, owing to error in plaque assays and from other sources, mixed infections with mutants in the same viral gene will often yield CIs of slightly greater than one, and the practical cutoff must be determined empirically for a given viral system. An example of complementation analysis is provided in the eBook.

Qualitative complementation tests have also been devised for use with both bacterial and mammalian viruses.^{8,12,71,118}

These qualitative tests are much easier to perform than quantitative tests and in practice are just as reliable. In general, the tests are designed such that bacterial lawns or eukaryotic cell monolayers are infected either singly or with two viruses under nonpermissive conditions and at relatively low moi. The moi must be high enough so that numerous cells are doubly infected in the mixed infection, although low enough so that most cells are uninfected and a lawn or monolayer is maintained. Complementing mutant pairs produce plaques or cleared areas under nonpermissive conditions, whereas noncomplementing mutant pairs do not. An example of a qualitative complementation test is shown in Figure 2.10. A theoretical disadvantage of the qualitative test is that it does not discriminate between complementation and recombination. In some cases, recombination between mutants in the same complementation group under nonpermissive conditions is sufficiently rare, thus the qualitative test is reliable.¹³ If recombination does occur under nonpermissive conditions, false positives occur in the qualitative test and the number of complementation groups is overestimated.⁶⁵ Nevertheless, negative tests are still a reliable measure of noncomplementation.

Complementation analysis has been of tremendous benefit in sorting mutants in most, but not all, viral systems. A notable exception is poliovirus, where complementation between temperature-sensitive mutants *in vivo* is not observed. The lack of complementation in picorna viruses may be related to the unique mechanism of viral gene expression, in which all protein products are produced from a polyprotein precursor by proteolytic cleavage. If individual temperature-sensitive mutants affect structure, synthesis, or cleavage of the polyprotein precursor, they may behave as if they all belong to a single complementation group, even though they may map to different protein end products.

As a concept, complementation impacts broadly on virology and is not limited simply to the grouping of conditionally lethal mutants into genes. For example, the growth of engineered host-range deletion mutants in essential virus genes, discussed previously, relies on complementation of the missing viral function by an engineered cell line that expresses the wild-type viral gene product. In addition, the accumulation of defective virus genomes at high multiplicity passage, also discussed earlier, results from a complementing helper function provided by wild-type virus.

FIGURE 2.10. Qualitative complementation test. This test was done to confirm the composition of two different complementation groups in vaccinia virus, one in gene *D5* (rows *A* and *B*) and one in gene *G2* (rows *C* and *D*). Candidate mutants in gene *D5* are *Cts24*, *Dts12*, *Dts38*, and *Dts56*. Candidates in gene *G2* are *Cts56*, *Dts22*, and *Dts42*. *Cts15* and *Dts33* were known to map to different genes and were used as positive controls for complementation. Monolayers of the African green monkey kidney cell line BSC40 grown in a 24-well dish were infected at very low moi (~ 0.03 pfu/cell) with individual mutants or mutant pairs. The dish was incubated at a nonpermissive temperature (40°C) for 3 days and stained with crystal violet. The stained dish is shown at the **top**, and a key to the infections is shown at the **bottom**. Mixed infections in rows *A* and *B* represent all possible pairwise combinations of gene *D5* temperature-sensitive mutants along with the *Cts15* positive control, and mixed infections in rows *C* and *D* represent all possible pairwise combinations of gene *G2* temperature-sensitive mutants along with *Cts15* and *Dts33* positive controls. The absence of plaques confirms that mutants reside in the same complementation group. Control single infections produced no plaques (not shown). (Reprinted from Lackner CA, D'Costa SM, Buck C, et al. Complementation analysis of the dales collection of vaccinia virus temperature-sensitive mutants. *Virology* 2003;305:240–259, © 2003, with permission from Elsevier.)

Recombination and Reassortment

Recombination describes a process by which nucleic acid sequences from two genotypically different parental viruses are exchanged so that the progeny contain sequences derived from both parents. In viral systems, there exist three distinct mechanisms of recombination, dictated by the structures of

the viral genomes. For DNA viruses, recombination occurs by the physical breakage and rejoining of parental DNA molecules through regions of sequence homology, in a fashion similar or identical to the same process in bacteria or higher organisms. For RNA viruses containing segmented genomes, gene exchange occurs primarily through reassortment of individual parental genome segments into progeny viruses, although intragenic recombination has been reported for orthomyxoviruses, reoviruses, and bunyaviruses.^{97,101,103,115,120}

For most nonsegmented RNA viruses, recombination appears to be a much less frequent event compared with DNA viruses. Recombination has been observed in several ssRNA virus families representing both positive and negative sense genomes; picornaviruses, coronaviruses, togaviruses, and retroviruses display relatively efficient recombination.^{2,45,56,66,67,73,74,136} Recombination in RNA viruses is thought to occur during replication via *copy choice*, namely switching templates during replication such that the newly synthesized genome contains sequence from two different parental molecules.¹⁶ Historically, recombination has been used to construct genetic maps of virus mutants and to construct novel virus genotypes. Although recombination mapping has been largely replaced by physical mapping techniques such as marker rescue, a technical knowledge of recombination mapping can contribute to an appreciation of the complexity of genetic interactions between viruses.

The methods used to determine recombination frequencies are the same regardless of genome structure or mechanism of recombination. As with complementation, the quantitative test to determine recombination frequency between two mutants, called a *two-factor cross*, is a two-step procedure, but in this case co-infections are first done under conditions permissive for replication, then the fraction of recombinants relative to the total virus yield is quantitatively assessed by plaque titration. Specifically, cells are first infected with two different virus mutants at high moi so that all cells are co-infected with both mutants, and infected cells are incubated under permissive conditions so that both mutants have maximum opportunity for interaction, for an interval sufficient to achieve maximum virus yield. Single high moi infections under permissive conditions are performed as controls. Virus is then harvested, yields are quantified by plaque titration under both permissive and nonpermissive conditions, and a recombination frequency (RF) is calculated according to the following formula:

$$\frac{\text{yield}(A+B)_{\text{np}} - \text{yield}(A)_{\text{np}} - \text{yield}(B)_{\text{np}}}{\text{yield}(A+B)_{\text{p}}} \times 2 \times 100\% = \text{RF},$$

where *A* and *B* represent individual virus mutants, and the subscripts *p* and *np* represent the conditions, permissive or nonpermissive, under which the virus yields were plaque titrated. The first term in the numerator, $\text{yield}(A+B)_{\text{np}}$, quantifies wild-type virus emerging from the mixed infection, including both recombinants and revertants, because only wild-type virus will grow in the plaque assay done under nonpermissive conditions. The second and third terms in the numerator, $\text{yield}(A)_{\text{np}}$ and $\text{yield}(B)_{\text{np}}$, quantify wild-type virus emerging from the control single infections, providing a measure of reversion in each of the two mutants. Subtraction of the revertants from the total yield of wild-type virus leaves a

measure of recombinants only in the numerator. The denominator, $\text{yield}(A + B)_p$, quantifies the total virus yield from the mixed infection including both wild-type and mutant virus, because all input virus types will grow in the plaque assay done under permissive conditions. The quotient is multiplied by a factor of two to account for unscored progeny representing the reciprocal of the wild-type recombinants, namely double mutants, and converted to a percent.

Recombination mapping in DNA viruses relies on the assumption that the frequency of recombination between two genetic markers is proportional to the distance between the two markers. For several DNA viruses, observed recombination frequencies comprise a continuous range from less than 1% up to a theoretical maximum of 50%, allowing for construction of linear genetic maps.³⁸

In viruses with segmented genomes, recombination between markers on the same segment is rare but reassortment of segments is extremely efficient; thus, recombination is effectively an all or none phenomenon, with markers on the same segment displaying no recombination, and markers on different segments displaying very high levels of recombination.¹⁰² For these reasons, genetic exchange in segmented RNA viruses is commonly referred to as reassortment rather than recombination. Reassortment analysis for segmented viruses is useful for determining whether or not two mutants map to the same genome segment but cannot be used to determine the order of markers on a given segment. Mutants can be mapped to individual RNA segments by performing *intertypic* crosses between virus types that differ in the electrophoretic mobility of each RNA segment. Specifically, if crosses are performed between a wild-type virus of one type and a mutant virus of another type and numerous wild-type progeny analyzed, one segment bearing the wild-type allele will be conserved among all the progeny, whereas all other segments will display reassortment.¹⁰²

Marker Rescue

Marker rescue is a physical mapping technique that measures directly whether a given virus mutation maps within a specific subfragment of a virus genome. The use of marker rescue is confined to DNA viruses where homologous recombination takes place and has been of enormous value in these systems. The application of the technique varies somewhat depending on the virus system under study; however, the general principles are the same. Specifically, full-length mutant viral genomic DNA plus a wild-type DNA genomic subfragment, either a cloned DNA molecule or a PCR product, are introduced into cells under conditions permissive for recombination and for wild-type virus replication. For viruses that contain infectious DNA, such as herpesviruses,¹¹⁷ adenoviruses,⁴² and polyomaviruses,^{72,89} the mutant genomic DNA and the wild-type genomic subfragment may be co-transfected into cells. For viruses containing noninfectious genomic DNA, such as poxviruses,¹²² the mutant DNA must be introduced into cells by infection with the mutant virus, which is then followed by transfection with the wild-type DNA subfragment. In either case, the protocol allows for homologous recombination between the mutant genome and the wild-type DNA subfragment. If the wild-type DNA subfragment contains the wild-type allele for the mutation, the recombination can exchange the wild-type for the mutant sequence in the

mutant genome, creating wild-type virus. Conversely, if the wild-type fragment does not contain the wild-type allele for the mutation, no wild-type virus, above a background of revertants, will be created in the experiment. The presence of wild-type virus can be assayed using either a two-step or a one-step protocol. In the two-step protocol, depending on the nature of the mutation being rescued, infected and/or transfected cells are incubated under permissive conditions to facilitate recombination and replication, or nonpermissive conditions to select for wild-type recombinants, then wild-type virus yields are quantified by plaque titration under nonpermissive conditions. In the one-step protocol, the infection and/or transfection is done so that only a small fraction of the cells in a monolayer are infected, and cells are then incubated under nonpermissive conditions such that wild-type virus formed during a successful rescue will form plaques on the monolayer.¹²² In short, regardless of the precise method used, conversion or *rescue* of mutant virus to wild-type with a given wild-type DNA fragment means that the mutation maps within that fragment. Initial marker rescue mapping experiments may be facilitated by the use of a few large but overlapping wild-type DNA fragments, and fine mapping may be accomplished with fragments as small as a few hundred nucleotides. Marker rescue mapping has completely replaced recombination mapping as a method for mapping mutations in DNA viruses, and precise genetic maps of several DNA viruses have now been constructed.

Reverse Genetics

Prior to the advent of recombinant DNA and DNA sequencing technologies, classical genetic analysis, namely random isolation and characterization of virus mutants, was one of the few effective methods for identifying, mapping, and characterizing virus genes, and the only method for obtaining virus mutants. With the current ready availability of genomic sequences for virtually all prototypical members of each virus family and a versatile package of genetic engineering tools, the experimental landscape has changed completely. One can now conduct a genetic analysis with a reasonably complete foreknowledge of the genetic structure of the virus, focus attention on individual genes of interest, and deliberately engineer mutations in genes to study their function. Termed *reverse genetics*, this process has come to dominate the genetic analysis of viruses. Reverse genetics covers a broad range of activities ranging from engineering a single nucleotide substitution in a target gene to engineering chimeric viruses to be used as gene therapy vectors, oncolytic vectors, or vaccines. Currently, virtually every significant human viral pathogen can be engineered using reverse genetic approaches. Perhaps one of the most impressive feats in reverse genetics is the resurrection of the deadly 1918 pandemic strain of influenza using genome sequences derived from archived formalin-fixed lung autopsy materials and from frozen, unfixed lung tissues from an Alaskan influenza victim who was buried in permafrost.¹²⁵

Reverse genetic analysis involves two distinct considerations: strategies for design of a given mutation and strategies for incorporation of mutations into virus. The principles governing these strategies highly depend on the structure of a given viral genome and the strategy of virus replication, and thus vary in the extreme. However, some general principles can

be identified, which are discussed next, accompanied by a few specific examples to illustrate the general principles.

Incorporation of Mutations into Virus

The methods used for incorporation of mutations into a virus depend on several features of the individual virus under consideration, including genome size, whether or not the nucleic acid is infectious, whether the genome is composed of DNA or RNA or replicated via reverse transcription, and whether replication is nuclear or cytoplasmic.

DNA VIRUSES AND REVERSE TRANSCRIBING VIRUSES

With the exception of poxviruses, which because of their cytoplasmic site of replication must carry virion-encapsidated transcription enzymes into cells during infection, virtually all DNA virus genomes (see Table 2.1) are infectious. Likewise, double-stranded DNA (dsDNA) comprising the genomic sequences of reverse transcribing viruses that package RNA (retroviruses) or DNA (hepadnaviruses) genomes are also infectious. Thus, in these cases, the incorporation of a mutation into the virus genome is essentially an exercise in molecular cloning, and pure mutant virus is produced by transfection of the cloned mutant genome into cultured cells. In practice, the herpesvirus genome is sufficiently large such that manipulation as a full-length genomic clone presents

some difficulties, and therefore incorporation of mutations into the viral genome is often done by co-transfecting cells with full-length genomic viral DNA along with a DNA fragment containing the desired mutant allele flanked by wild-type DNA sequences. Replication is launched from the transfected infectious wild-type genomic DNA, and homologous recombination between the co-transfected mutant DNA fragment and the wild-type genome incorporates the mutant allele into a fraction of the replicating wild-type genomes¹³⁹ (Fig. 2.11). A similar protocol is applied to engineering poxviruses; however, because poxvirus DNA is noninfectious, virus replication must be initiated by infection with intact virus. In its simplest form, this protocol entails infection with virus bearing the wild-type target genome followed by transfection with a DNA fragment containing the desired mutation flanked by wild-type DNA sequences⁹⁵ (Fig. 2.12; identical to the protocol for marker rescue described earlier). Similar to the herpesvirus co-transfection protocol just described, homologous recombination catalyzed by viral enzymes results in incorporation of the mutant allele into a fraction of the wild-type infecting genomes. An alternate protocol for constructing poxvirus recombinants involves first infecting cells with a replication defective, nonhomologous helper poxvirus, followed by transfection with either a cloned full-length mutant genome or a mixture of fragments comprising the desired engineered genome.^{23,105,137} The helper virus provides

FIGURE 2.11. Reverse genetics with large double-stranded DNA viruses containing infectious genomes. Wild-type full-length infectious genomic viral DNA (blue line) is co-transfected into cells along with a subgenomic viral DNA fragment (green line) containing the desired mutation (red X). Homologous recombination between the co-transfected viral DNAs takes place within the cell catalyzed by viral and/or cellular enzymes. The recombinant genome is replicated and packaged to yield recombinant virus (mixed with wild-type virus replicated from unrecombined genomes).

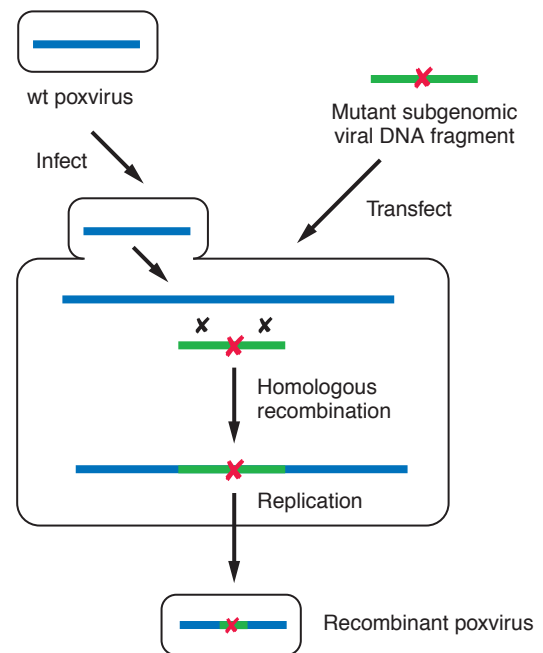

FIGURE 2.12. Reverse genetics with large double-stranded DNA viruses containing noninfectious genomes (poxviruses). Cells are infected with virus containing a wild-type DNA genome (blue line) and transfected with a subgenomic viral DNA fragment (green line) containing the desired mutation (red X). Homologous recombination between the infecting viral DNA and co-transfected fragment takes place within the cell catalyzed by viral enzymes. The recombinant genome is replicated and packaged to yield recombinant virus (mixed with wild-type virus replicated from unrecombined genomes).

enzymes critical for launching replication of the transfected full-length mutant viral DNA genome, or for homologous recombination among transfected subgenomic fragments to assemble and launch replication of the desired virus.

When mutants are engineered in cloned, infectious genomes, only the mutant allele of the target gene is present in the construction, all virus recovered from the transfection will be mutant, and no selection or screen for mutants is required. However, in situations where *in vivo* homologous recombination has been used to incorporate the cloned mutation into a wild-type genome, such as in poxviruses or herpesviruses, both mutant and wild-type viruses emerge from the mutant construction protocol, and thus a screen or selection is required to identify the mutant of interest. For mutations in nonessential genes, this may be a relatively straightforward matter of inserting into the target gene a color marker such as β -galactosidase¹³⁹ or green fluorescent protein¹⁹ to facilitate a screen, or inserting a dominant selectable marker such as *Escherichia coli* guanine phosphoribosyltransferase,³⁰ to facilitate a selection. For conditionally lethal phenotypes such as temperature sensitivity, although techniques exist that enrich for recombinant viruses, mutant isolation ultimately relies on a screen of individual mutants for differential growth under permissive and nonpermissive conditions.⁴⁷ The use of full-length clones of herpesvirus and vaccinia virus obviates the need for *in vivo* recombination, and thus only mutant virus will be recovered after transfection or reactivation of an engineered, mutant genome, and no mutant screen or selection is necessary.^{24,88}

RNA VIRUSES

The genomes of positive sense, ssRNA viruses (see Table 2.1) are infectious; therefore, as with most DNA viruses, the engineering of mutant viruses is largely an exercise in molecular cloning, yet formidable for large RNA viruses such as coronaviruses.¹³⁸ To recover infectious virus, complementary DNA (cDNA) clones of mutant genomes may be transfected directly into cultured cells or transcribed *in vitro* into positive sense RNA that is then transfected into cells. Virus replication is launched by translation of the transfected RNA *in vivo*, resulting in recovery of only mutant virus. A good example of the application of this technology is the directed construction of temperature-sensitive mutants in poliovirus.²²

Negative sense ssRNA viruses must package in the virion a virus-coded RNA-dependent RNA polymerase so that the genome, in the form of a nucleocapsid, can be transcribed into mRNA immediately following infection. Thus, negative sense ssRNA virus genomes are not infectious, and engineering these viruses becomes more of a challenge. Generally, the strategy consists of transfection of cells with multiple plasmids, some of which are transcribed into genome-length RNAs (encoding the desired genotype) and some of which direct expression of proteins required for genome replication, specifically a nucleocapsid protein and proteins comprising the viral RNA-dependent RNA polymerase. The expressed nucleocapsid protein encapsidates the transcribed genomic RNA, and this nucleocapsid can then be transcribed into mRNA by the expressed viral RNA polymerase, thus launching the infection and ultimately yielding pure virus of the desired genotype. Historically, the requirements for “rescue” of virus from cloned fragments are different for the segmented negative sense ssRNA orthomyxo-

viruses compared to most nonsegmented negative sense ssRNA viruses, namely rhabdoviruses, paramyxoviruses, and filoviruses, comprising most of the order *Mononegavirales*. The differences are attributable, at least in part, to the fact that the orthomyxoviruses replicate in the nucleus, whereas most of the viruses in the order *Mononegavirales* replicate in the cytoplasm. Specifically, for the orthomyxoviruses,⁹³ genome segments are cloned so that they are transcribed from a polymerase I promoter to yield the negative sense genomic RNA, and the replication proteins are cloned so that they are transcribed from a polymerase II promoter to yield mRNA. Both polymerases are expressed in the cell nucleus so that after transfection of the plasmids, the viral RNAs are synthesized in the appropriate cellular compartment. The number of plasmids required for rescue can be minimized by flanking each genome segment with a polymerase I promoter at the 3' end and a polymerase II promoter at the 5' end so that each plasmid yields both a negative sense genomic RNA and a positive sense mRNA (Fig. 2.13). For most *Mononegavirales* viruses,¹⁵ rescue is best achieved if synthesis of both the genomic RNA and the replication proteins are driven by the bacteriophage T7 RNA polymerase, which localizes efficiently to the cell cytoplasm. The T7 RNA polymerase can be supplied either by infection with a poxvirus expressing T7 RNA polymerase, by using a cell line containing a stably integrated copy of the T7 RNA polymerase gene, or by transfection of an additional plasmid designed to express the enzyme. An additional (counterintuitive) requirement for rescue of *Mononegavirales* viruses is that the plasmid encoding the genomic RNA is configured so that it is initially transcribed to yield positive sense, antigenomic RNA, which is then encapsidated with expressed nucleocapsid protein, and replicated into encapsidated negative sense genomic RNA, which is in turn transcribed into mRNAs to launch the infection (Fig. 2.14). The use of a plasmid that expresses the negative sense genomic RNA compromises the rescue, presumably because the negative sense genomic RNA will hybridize in the cytoplasm with the positive sense mRNAs for replication proteins, thus repressing their expression. Despite these generalities, examples exist of rescue of cytoplasmic *Mononegavirales* viruses using polymerase I or polymerase II promoters.⁸³

The segmented, double-stranded (dsRNA)-containing, cytoplasmic reoviruses can be rescued using a protocol similar to that used for *Mononegavirales*.⁶⁹ Specifically, cDNAs of individual segments are cloned downstream from a bacteriophage T7 promoter, each yielding an RNA product that doubles as mRNA and the positive strand template for genomic dsDNA. Transfection of these plasmids into cells expressing T7 RNA polymerase results in synthesis of genomic segments and replication proteins, ultimately yielding pure virus of the desired genotype. T7 RNA polymerase can be supplied by any of the previously mentioned methods: co-transfection of an expression plasmid, expression from a stably integrated chromosomal gene, or infection with a poxvirus expressing the enzyme. Interestingly, this protocol does not work for all reoviruses, most notably the important human pathogen rotavirus, which must still be engineered using more complex helper-mediated protocols.¹²⁴

Mutation Design

Design of mutations for use in virology is problematic only if the gene in question is essential, necessitating isolation of

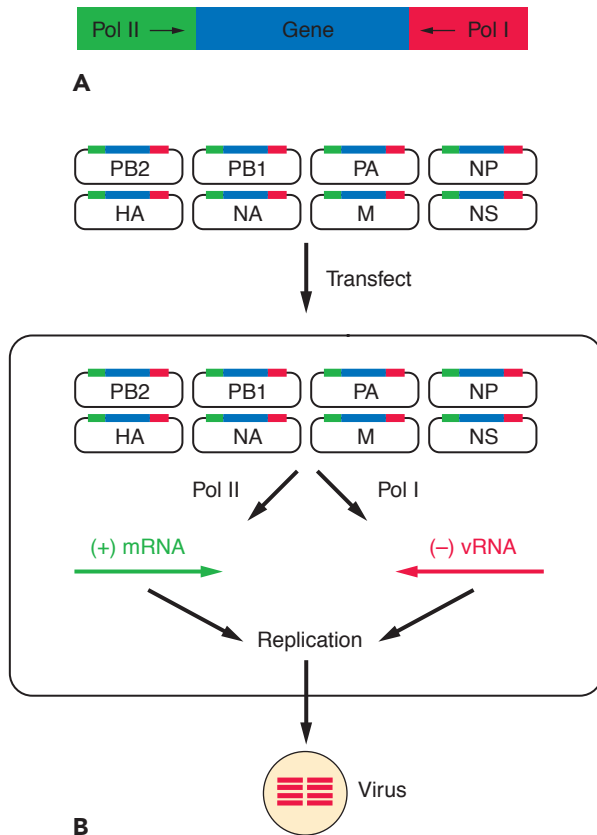

FIGURE 2.13. Reverse genetics with orthomyxoviruses (influenza).

A: Detailed structure of cloned viral genes. Coding sequences for each viral gene (blue) are cloned flanked by an RNA polymerase II transcriptional promoter (green) at the upstream (5') end and an RNA polymerase I transcriptional promoter (red) at the downstream (3') end. **B:** Reverse genetic protocol. Cells are transfected with eight plasmids together representing the entire complement of virus genes. Transcription in the nucleus with polymerase II produces positive sense messenger RNAs (green) that are translated into viral proteins including the polymerase (PB1, PB2, PA) and nucleocapsid protein (NP). Transcription from the polymerase I promoter produces negative sense genomic viral RNAs (red), which are then replicated by the viral replication proteins. Further transcription, replication, and encapsidation produces virus.

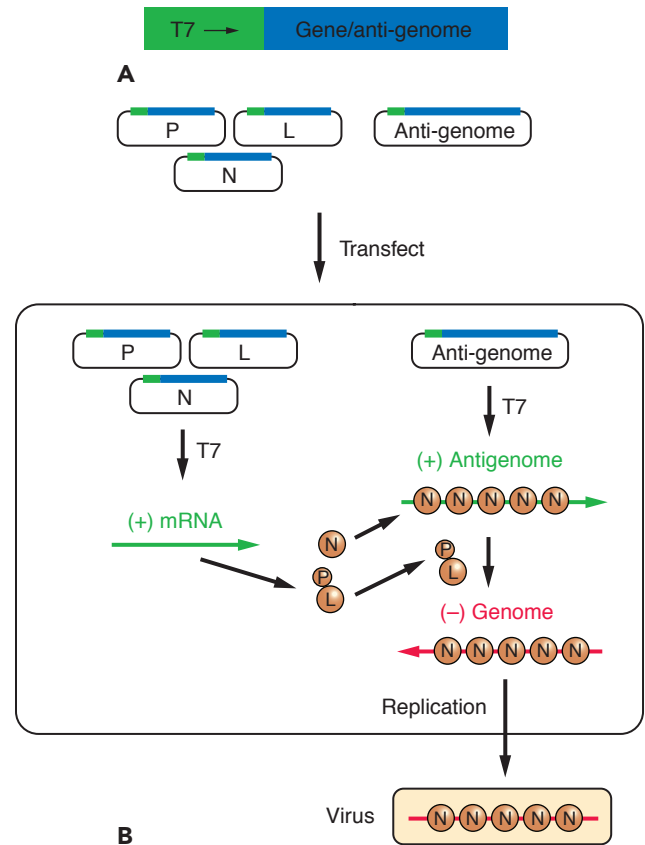

FIGURE 2.14. Reverse genetics with viruses in the order *Mononegavirales*.

A: Detailed structure of cloned genes. Coding sequences for replication proteins or the full-length viral genome (blue) are cloned downstream from a bacteriophage T7 transcriptional promoter (green). **B:** Reverse genetic protocol. Cells are transfected with four plasmids, three of which encode replication proteins (P, L, and N) and one of which contains the full-length viral genome oriented such that transcription yields a positive sense antigenomic RNA. Transcription by T7 RNA polymerase (usually encoded by an engineered stably integrated copy in the cell nucleus) yields messenger RNA for the replication proteins (green) plus positive sense antigenomic viral RNA (green). Translation of the messenger RNAs provides nucleocapsid protein (N), which encapsidates the antigenomic RNA. Antigenomic nucleocapsid is replicated by the viral polymerase (L and P) to yield negative sense genomic viral nucleocapsid (red viral RNA encapsidated with brown N protein), which can be further transcribed and replicated to yield recombinant virus.

a conditionally lethal mutation. For genes that are nonessential, mutation design is a simple matter of engineering a null mutation (e.g., a deletion, insertion, or nonsense mutation) into the cloned gene sequence. Three basic types of engineered conditionally lethal mutations are currently in use: host-range deletion mutants, which rely on the availability of a complementing host cell; temperature-sensitive mutants constructed by clustered charge to alanine scanning; and artificially induced gene regulation. For host-range deletion mutants, the primary problem is construction of a host cell that expresses the target gene in a fashion appropriate for complementation of a null mutant in the virus. Once a cell line has been isolated, construction of the cloned mutation in the virus gene follows the same principles governing construction of a null mutation in a nonessential gene. The fundamental problem in

creating temperature-sensitive mutations is that it is currently impossible to predict from primary amino acid sequence or even from three-dimensional protein structure what type of mutation will render a protein temperature sensitive. This difficulty has been partially overcome with the use of clustered charge to alanine scanning mutagenesis, in which clusters of three or more charged residues in the primary amino acid sequence of a protein are all changed to alanine.¹³² In theory, charge clusters are likely to reside on the surface of the protein where they may facilitate protein–protein interactions, and neutralization of the charge by replacement with alanine may weaken such interactions without seriously disrupting the three-dimensional conformation of the protein. In practice, as

much as 30% of clustered charge to alanine scanning mutants prove to be temperature sensitive *in vivo*, and this mutagenesis technique has been successfully used to construct temperature-sensitive mutants of both picornaviruses and poxviruses.^{22,48} Lastly, conditionally lethal mutants have been constructed in poxviruses by placing essential genes under bacterial operator-repressor control in the viral genome.^{52,106,123}

Defective Interfering Particles

Interference refers generally to a phenomenon whereby infection by one virus results in inhibition of replication of another virus.³⁴ Defective interfering (DI) particle-mediated interference was first described by von Magnus,¹³⁰ who noted that serial undiluted passage of influenza virus resulted in a dramatic decrease in infectious titer while the number of particles remained constant. Essentially the same phenomenon was subsequently observed in a wide variety of RNA and DNA animal viruses, as well as in plant and bacterial viruses.⁵⁷ The mechanism of interference in each case is similar, namely virus stocks accumulate *DI particles*. DI particles are virus particles that contain genomes that are grossly altered genetically, usually by significant deletion of essential functions, but nevertheless retain critical replication origins and packaging signals, allowing for amplification and packaging in co-infections with complementing wild-type *helper* virus. DI particles usually display a replication advantage relative to wild-type virus, resulting from increases in the copy number or efficiency of replication origins. DI particles actively inhibit replication of wild-type virus, presumably by competing for limiting essential replication factors. Study of DI particles has provided significant insight into the viral replication, particularly structure and function of replication origins.

Phenotypic Mixing and Pseudotypes

If two heterologous viruses infect the same cell, then depending on the relatedness of the two viruses, the opportunity exists for packaging of either virus genome into a nucleocapsid or envelope comprised wholly or in part of structural proteins encoded by the heterologous virus. This phenomenon, termed *phenotypic mixing*, has been observed in mixed infections in a laboratory setting using both nonenveloped and enveloped viruses. Phenotypic mixing is a transient phenomenon, because infection of a cell with a single phenotypically mixed particle will result in replication and assembly only of viruses that reflect the infecting genome. In mixed infections with nonenveloped viruses, phenotypic mixing has been observed between closely related adenoviruses, reoviruses, and picornaviruses.^{54,103,135} Phenotypic mixing has been observed between picornaviruses as distantly related as echovirus 7 and coxsackievirus A9.⁵⁸ In the case of enveloped viruses, phenotypic mixing consists of packing the nucleocapsid of one virus within an envelope of a heterologous virus, and the resulting viruses are called *pseudotypes*. Pseudotype formation among enveloped viruses is relatively promiscuous, especially among retroviruses and rhabdoviruses.¹⁴¹ For example, pseudotypes have been formed that contain retrovirus envelope antigens combined with genomes from rhabdoviruses, paramyxoviruses, orthomyxoviruses, or herpesviruses. Conversely, pseudotypes have been formed that contain a rhabdovirus genome combined with envelope antigens from togaviruses,

retroviruses, bunyaviruses, arenaviruses, paramyxoviruses, orthomyxoviruses, herpesviruses, or poxviruses. Historically, phenotypic mixing experiments have contributed to understanding virus structure and assembly. Currently, the concept of phenotypic mixing and pseudotype formation is of critical utility in packaging and delivery of virus vectors, particularly because phenotypic mixing permits the tropism of a virus particle to be manipulated.⁶² Lastly, there has been some speculation that phenotypic mixing may actually play a role in a natural setting, serving to maintain otherwise unfit genomes within a quasispecies over time.¹³⁴

Principles of Virus Structure

How Virus Structures Are Studied

Symmetry of Viruses

Structures of Closed Shells

- Quasiequivalent Icosahedral Arrangements
- Nonequivalent Icosahedral Surface Packings
- Frameworks and Scaffolds
- Elongated Shells
- Multishelled Particles
- Rearrangements in Surface Lattices
- Two Recurring Globular Domains in Icosahedral Capsid Proteins

Self-Assembly and Cleavage Steps

Genome Packaging

- Positive-Strand RNA Genomes
- dsDNA Genomes
- dsRNA Genomes
- Negative-Strand RNA Genomes

Viral Membranes

- Budding
- Internal Structures
- Surface Envelope Proteins

Structural Biology of Virus Entry

- Receptor Binding
- An Irreversible Step Between Assembly and Entry
- Membrane Fusion
- Penetration by Nonenveloped Viruses

Virus particles are carriers of genetic material from one cell to another. They are, in effect, extracellular organelles. They contain most or all of the molecular machinery necessary for efficient and specific packaging of viral genomes, escape from an infected cell, survival of transfer to a new host cell, attachment, penetration, and initiation of a new replication cycle. In many cases, the molecular machinery works in part by subverting more elaborate elements of a host cell's apparatus for carrying out related processes.

A number of organizational modes have evolved to perform the functions just outlined. The most critical distinction, from a structural perspective, is between *enveloped* viruses—those with lipid-bilayer membranes—and *nonenveloped* viruses—those without such membranes. Both categories include well-known human pathogens. Examples of the former are human immunodeficiency virus (HIV) and

influenza virus; examples of the latter, poliovirus and papillomavirus. Enveloped viruses have, in their lipid bilayer, an impermeable barrier between their genomes and the outside environment, reducing the need for continuity of any protein layer. Nonenveloped viruses require a tightly packed shell to exclude nucleases or other sources of genomic damage.

For the structure of any virus particle, a central constraint is that the information needed to specify its macromolecular components must not exhaust the genetic capacity of the packaged genome. This requirement for genetic economy is in practice quite stringent. For example, consider a very simple genome of 5 kb, enough to encode about 1,600 amino acid residues, if reading frames do not overlap. A tightly condensed single-stranded RNA or DNA of this size will occupy a spherical volume about 90 Å in radius. To protect it with a gap-free protein shell, 30 Å thick, would require roughly 25,000 amino acid residues—far more than the viral nucleic acid can encode. The shell of a nonenveloped virus with even a very small genome must therefore contain a large number of identical protein subunits—at least 60, if the coat-protein gene is to use up less than 25% of the coding capacity in the enclosed nucleic acid. As explained later, an important consequence of this observation (first made by Crick and Watson⁵⁶ even before a triplet code had been established) is that virus particles, or their substructures, are usually highly symmetric.

HOW VIRUS STRUCTURES ARE STUDIED

Electron microscopy is the most direct way to determine the general morphology of a virus particle. Traditional thin-sectioning methods are useful for examining infected cells and larger, isolated particles. The thickness of a section and the coarseness of staining methods limit resolution to about 50 to 75 Å, even in the best cases. (*Resolution* means the approximate minimum size of a substructure that can be separated in an image from its neighbor. Recall that one atomic diameter is 2.3 Å; an α -helix, 10 Å; and a DNA double helix, 20 Å.) Negative staining, with uranyl acetate, potassium phosphotungstate, or related electron-dense compounds, gives somewhat more detailed images of isolated and purified virus particles. Viruses embedded in negative stain are often relatively well preserved. The electron beam destroys the particle itself very rapidly, but it leaves the dense “cast” of stain undamaged for much longer. If the particle is fully covered by the negative stain, the image contains contrast from both the upper and the lower surface of the particle, and visual interpretation of finer aspects of the image can be difficult.⁵⁷

FIGURE 3.1. Bovine papillomavirus (BPV), as seen by electron cryo-microscopy (cryoEM). In the foreground is a color rendering of the three-dimensional image reconstruction, based on the kinds of micrographs shown in the background picture. The circular inset at **lower right** illustrates that this reconstruction provides information that extends to a nearly atomic level of detail (*resolution*); it shows a small part of the density map that resulted from the image analysis and the fit to that map of parts of the L1 polypeptide chain. (See Grigorieff and Harrison⁹⁴ and Wolf et al.²⁴⁶)

Methods for preserving viruses and other macromolecular assemblies by rapid freezing to liquid nitrogen or liquid helium temperatures have permitted visualization of electron-scattering contrast from the structures in the particle itself and not just from the cast created by a surrounding layer of negative stain.¹⁰ Moreover, quantitative methods for image analysis, originally developed for studying negatively stained particles, have been applied effectively to such images. An advantage of such electron cryomicroscopy (cryoEM) is that regular images can be selected from a heterogeneous field, allowing study of unstable or relatively impure preparations. Advances during the decade preceding the current revision of this chapter have enabled cryo-EM three-dimensional density maps at resolutions that reveal molecular details—the tracing of a polypeptide chain and the orientations of large amino acid side chains.⁹⁴ One example is illustrated in Figure 3.1.²⁴⁶ Such *image reconstructions* are obtained by combining information from hundreds or thousands of different images of individual particles. The combination is possible because the particles of these viruses are all the same. When such uniformity is not present, for example, as in the case of a complete herpesvirus particle rather than an isolated nucleocapsid, then information from different particles cannot be combined. A *tomographic* tilt series of images from a single particle can be obtained (analogous to a computed tomography [CT] scan in medical radiography), but the resulting three-dimensional image is of much lower resolution, as electron damage limits its quality, even when the data are taken at liquid nitrogen or liquid helium temperatures (electron cryotomography, or cryoET). Tomographic reconstructions can nonetheless be very useful, as illustrated in Figure 3.2. In some cases, averaging the images of defined substructures within a tomogram or among many tomograms (e.g., the “spikes” on the surface of certain enveloped viruses) can yield a more detailed representation.

The information obtained from even the most elegant of electron microscopy methods still falls short of the atomic detail that often can be obtained by x-ray diffraction methods, if single crystals of the relevant structure can be prepared. It has been known since the 1930s that simple plant viruses, such as tomato bushy stunt virus (TBSV), can be crystallized,¹³ and the first x-ray diffraction patterns of such crystals were recorded as early as 1938.¹⁷ Crystallization of poliovirus and other important animal viruses showed that the approach could be extended to human pathogens.²¹³ The first complete high-resolution structure of a crystalline virus was obtained from TBSV in 1978,¹⁰⁷ and since then the structures of a number of animal, plant, and insect pathogens have been determined (for a compilation, see the VIPER website: <http://viperdb.scripps.edu>). Only very regular structures can form single crystals, and in order to study the molecular details of larger and more complex virus particles, it is necessary to “dissect” them into well-defined subunits or substructures. This dissection was originally done with proteases, by disassembly, or by isolation of substructures from infected cells. For example, the structure of the influenza virus hemagglutinin²⁴⁴—the first viral glycoprotein for which atomic details were visualized—was obtained from crystals of protein cleaved from the surface of purified virions²⁴³; the structure of the adenovirus hexon was obtained from excess unassembled protein derived from adenovirus-infected cells.¹⁸⁹ In the past two decades, this dissection has more commonly been carried out using recombinant expression (e.g., of a fragment of gp120 from HIV-1¹³¹). Most of the high-resolution structures of enveloped virus components described in this chapter—both surface glycoproteins and internal proteins—come from x-ray crystallographic analysis of recombinant gene products, often suitably truncated or otherwise modified to enable crystallization. A handful of atomic-level structures of virus components have come from nuclear magnetic resonance (NMR) spectroscopy,^{178,200} but application of that technique is limited to relatively small proteins or protein complexes.

SYMMETRY OF VIRUSES

Virus particles must assemble specifically and rapidly in an infected cell, as directed by the mutual interactions among their component protein subunits. Specificity requires a defined stereochemical relationship between contacting proteins. Because there are many copies of the same subunit, there must also be many repeating instances of the same kind of contact. This repetition—a consequence of the requirement for genetic economy described in the introductory section of this chapter—implies symmetry.

A rigorous definition of symmetry involves an operation, such as a rotation, that brings an object into self-coincidence. For example, if the ring of three commas in Figure 3.3A is rotated by 120 or 240 degrees, it will not be possible to recognize that a rotation has occurred (assuming that the commas are truly indistinguishable). The full symmetry of an object is defined by the collection of such operations that apply to it. In the case of protein assemblies, these operations can be rotations, translations, or combinations of the two. A symmetry axis that includes rotation by 180 degrees is called a *twofold axis* or a *dyad*; one with a 120-degree rotation (and, of course,

FIGURE 3.2. Electron cryotomography (cryoET) of herpes simplex virus type 1 (A),⁹⁸ vaccinia intracellular mature virion (B),⁵⁸ and HIV-1 (C).²³ Images in the **left-hand column** are single, projected images; those in the **middle column**, slices through the reconstructed tomogram; those on the **right**, cut-away surface renderings of the three-dimensional tomographic reconstructions. (Adapted from Cyrklaff M, Risco C, Fernandez JJ, et al. Cryo-electron tomography of vaccinia virus. *Proc Natl Acad Sci U S A* 2005;102:2772–2777.)

FIGURE 3.3. Icosahedral symmetry. A: Threefold symmetry: the three commas are related to each other by 120-degree rotations about the central axis, marked by a small triangle. **B:** Outline of an icosahedron, showing positions of some of the symmetry axes (imagined to extend from the center of the icosahedron to the point on the surface marked by the symbol): fivefold, threefold, and twofold axes are marked by pentagons, triangles, and an oval, respectively. **C:** An icosahedrally symmetric arrangement of commas on the surface of a sphere. For locations of symmetry axes, compare with panel B. **D:** Shaded surface view of an icosahedron.

FIGURE 3.4. Diagram of the tobacco mosaic virus (TMV) particle. The elongated “loaves,” with a groove for the RNA, represent the protein subunits. Three RNA nucleotides fit into the groove on each subunit. There are $16\frac{1}{3}$ subunits per turn of the right-handed helix (i.e., 49 subunits in three turns), with a rise of 23 Å as indicated. At the **lower right**, the surface lattice is drawn onto the outer particle. (Adapted from Caspar DL. Assembly and stability of the tobacco mosaic virus particle. *Adv Protein Chem* 1963;18:37–121.)

a 240-degree rotation as well) is called a *threefold axis*; and so forth. Note the distinction between shape and symmetry: the *shape* of an object refers to the geometry of its outline, whereas its *symmetry* refers to the operations that describe it. The set of commas in Figure 3.3A has threefold symmetry; so does an equilateral triangle, the beer-company symbol with three interlocked rings, and countless other objects with unrelated shapes.

As a first example, consider the rod-like coat of tobacco mosaic virus (TMV)¹²⁵ (Fig. 3.4). The helical arrangement of its protein subunits illustrates that symmetry is an important consequence of its assembly from many identical building blocks. If we look at the model of TMV, we find that a rotation of 22 degrees and a translation of 1.4 Å along the particle axis will superpose subunit 1 on subunit 2. But if the surfaces of subunit 2 are the same as those of subunit 1, the same rotation and translation must superpose subunit 2 on subunit 3, and so forth. The combination of rotation and translation that effects this superposition is a *screw axis*. Strictly speaking, the screw axis of TMV would only be an ideal symmetry operation if the helix were infinite. In practice, it is so long that we can neglect end effects.

In TMV, and probably in the nucleocapsids of negative-strand RNA viruses such as influenza and vesicular stomatitis

virus (VSV), the RNA winds in a helical path that follows the protein.¹²⁵ That is, the tubular package does not simply contain the RNA; it co-incorporates it. There are exactly three nucleotides per subunit in TMV, and they fit into a defined groove between the helically arrayed proteins. By contrast, the protein coat of a filamentous, single-stranded DNA (ssDNA) phage, such as M13, forms a sleeve that surrounds and constrains the closed, circular genome, without there being a specific way in which each subunit contacts one or more nucleotides.⁸⁷ Thus, there can be a nonintegral ratio of nucleotides to protein monomers.

The length of the packaged nucleic acid determines the length of virus particles such as TMV or M13. Structures such as the tail of bacteriophage lambda or T4 have a protein component that extends from the initiating structure at the base of the tail to the end connected to the head.³ The number of such polypeptide chains corresponds to the rotational symmetry of the tail.

Rod-like structures are not very efficient ways to package long genomes. At least one dimension of a helical assembly such as TMV grows linearly with the length of the packaged viral DNA or RNA, leading to awkwardly elongated particles. The number of subunits is likewise proportional to length. *Isometric* (i.e., essentially spherical) particles are more compact and more economical: if the nucleic acid condenses into the interior of the particle, then the diameter increases as the cube root of the genome length, and the number of required subunits as the genome length to the two-thirds power. Most animal viruses are roughly isometric.

Closed, isometric shells composed of identical subunits that interact through conserved, specific interfaces can have one of only three symmetries: the symmetry of the regular tetrahedron, the cube, or the regular icosahedron. These shells will accommodate 12, 24, or 60 subunits, respectively. The icosahedral shells are obviously the most efficient of the three designs: they use the largest number of subunits to make a container of a given size, and hence they use subunits of the smallest size and the smallest coding requirement. Tetrahedral and cubic symmetries have not appeared in any naturally occurring virus assemblies. Note the distinction between icosahedral symmetry and icosahedral shape. Not all objects with icosahedral symmetry have even the vague outline of an icosahedron; conversely, painting a single asymmetric object, such as a comma, on each face of an icosahedron, rather than three such objects related by the threefold axis through the middle of the face, would destroy the symmetry of the decorated object but would not affect its shape.

The diagram in Figure 3.3B shows the operations that belong to an icosahedrally symmetric object. They are a collection of twofold, threefold, and fivefold rotation axes. Placement of a single, asymmetric object on a surface governed by this symmetry leads to the generation of 59 others, when the various rotations are applied (Fig. 3.3C). One such object, one-sixtieth of the total shell, can therefore be designated as an *icosahedral asymmetric unit*, the fundamental piece of structure from which all the rest can be produced by the operations of icosahedral symmetry.

STRUCTURES OF CLOSED SHELLS

With a typical, compact protein domain of 250 to 300 amino acid residues, close to the upper limit for most single-protein

FIGURE 3.5. Canine parvovirus (CPV): a simple, icosahedrally symmetric virion. **A:** Icosahedron, viewed along a twofold axis, with diagrammatic representations of a protein subunit with a core domain (colored red on one of the subunits) and a projecting region (blue). Compare the subunits with the representation of commas in **B**, repeated from Figure 3.3 **C**. **C:** Ribbon diagram of the CPV protein subunit; the core domain (red) is a β -jelly-roll, from which emanate several loops that cluster to form a complex projecting region (blue). The simplified representation of the β -jelly-roll in **D** is in rainbow coloring, from blue at its N-terminus to red at its C-terminus. The eight strands are lettered B–I; the loops have the letters of the strands they connect. The projecting region of the CPV subunit comprises loops BC, EF, and GH. **E:** Icosahedron, as in **A**, but with a ribbon representation of one subunit; symbols for symmetry axes as in Figure 3.3B. **F:** Ribbon representation of all 60 subunits, with the subunit from **E** in blue and all others in gray.

domains, what sort of icosahedrally symmetric container can we construct? Suppose that the protein is so shaped that 60 copies fit together into a 30-Å thick shell with no significant gaps. Then the cavity within that shell will have a radius of about 80 Å, which can contain a 3- to 4-kb piece of single-stranded DNA or RNA, tightly condensed. A few, very simple virus particles indeed conform to this description. The parvoviruses (see Chapter 57) contain a 5.3-kb ssDNA genome, and their shells have 60 copies of a protein of approximately 520 residues (Fig. 3.5). The capsid protein therefore uses up about one-third of the genome. (“Capsid,” from the Latin *capsa*, “box,” designates the protein shell that directly packages DNA or RNA; “nucleocapsid” refers to the shell plus its nucleic acid contents.) Likewise, the satellite of tobacco necrosis virus (STNV) con-

tains 60 copies of a 195-residue subunit and a 1,120-bp single-stranded RNA (ssRNA) genome, of which over half is used for the coat protein.¹⁴¹ As the name implies, however, STNV is actually a defective virus, and it requires tobacco necrosis virus co-infection to propagate.

More complex viruses have evolved ways to make larger, icosahedrally symmetric shells without expending unnecessary genetic resources. The simplest, but least economical, is just to use several different subunits, each of “garden variety” size, to make up one icosahedral asymmetric unit. The picornaviruses (polioviruses, rhinoviruses, etc.) have 60 copies of three distinct proteins, VP1, VP2, and VP3, each between 230 and 300 amino acid residues, as well as 60 copies of a small internal peptide, VP4 (see Fig. 3.6). The shell has a cavity about 95 Å

FIGURE 3.6. Poliovirus. **Top:** The order of structural proteins in the polyprotein encoded by the viral RNA. These domains are at the N-terminal end of the polyprotein, which is modified by myristoylation (Myr). The viral protease that cleaves between VP0 (= VP4 + VP2) and VP3 and between VP3 and VP1 is encoded by a region 3' to the region that encodes the structural proteins; the VP4-VP2 cleavage is autolytic and occurs only after assembly of the virion precursor. **Middle:** Surface representation of the virus particle, with colors as in the diagram at the top. Two successively "exploded" views of an icosahedral asymmetric unit (*protomer*) are shown next to the surface rendering. VP1, VP2, and VP3 each have a central β -jelly-roll, with variable interstrand loops and variable N- and C-terminal extensions. The rainbow-colored β -jelly-roll below the surface view is repeated from Figure 3.5D. **Bottom:** Side-by-side views of the β -jelly-roll domains of VP1, VP2, and VP3 to illustrate their congruence.

in radius, which holds an RNA genome of 7.5 to 8 kb. The picornaviruses thus expend about one-third of their genome to encode the structural proteins of the virion. (The term *virion* means *virus particle*, generally implying the mature, infectious structure.) We note here two other important features of picornavirus molecular architecture. First, the folded structures of VP1, VP2, and VP3 all have the same kernel—a domain known as a *jelly-roll β -barrel* (Figs. 3.5 and 3.6). The single subunits of the parvoviruses and of STNV have the same basic fold. It is a module particularly well suited to the formation of closed, spherical shells because of its block-like, trapezoidal outline, but its prevalence among viral subunits may be evidence of a deeper evolutionary relationship. A second noteworthy feature of picornavirus design is that arm-like extensions of the subunits tie together the assembled particle (Fig. 3.6). The importance of scaffold-like intertwining of subunit arms was first discovered in the simple plant viruses.¹⁰⁷ In effect, folding of part of the subunit and assembly of the shell are concerted processes.

Quasiequivalent Icosahedral Arrangements

A more economical way to build shells from more than 60 average-sized, identical subunits was described by Caspar and Klug³⁵ in 1961. It is illustrated by the diagram of 180 commas in Figure 3.7. The commas have similar interactions (head-to-head in pairs; neck-to-neck in rings of three; tail-to-tail in rings of five or six), but they fall into three sets, designated A, B, and C. If the commas are taken to represent proteins, then the conformational differences between A and B positions, for example, involve the differences between rings of five and rings of

FIGURE 3.7. Quasiequivalent arrangement of 180 commas, in a $T = 3$ icosahedral surface lattice on a sphere. Compare Figure 3.3C, a $T = 1$ arrangement of 60 commas with icosahedral axes oriented similarly. The three quasiequivalent positions within a single icosahedral asymmetric unit are shown in blue, red, and green and labeled A, B, and C, respectively, in two of the asymmetric units.

six, for contacts involving the parts of the proteins symbolized by the tails. Caspar and Klug³⁵ suggested that protein subunits might have the sort of flexibility or capacity for conformational switching needed to accommodate somewhat different packing environments without sacrificing specificity. They postulated that viruses with more than 60 chemically and genetically identical subunits might exhibit the sort of near equivalence seen in the A, B, and C conformers in the comma illustration. They called this sort of local distortability, which might conserve much of the specificity and character of the protein contacts, *quasi-equivalence*.

A number of plant and animal viruses, such as TBSV¹⁰⁷ and Norwalk virus,¹⁸² conform to this description of quasiequivalent arrangements (Fig. 3.8). In TBSV and Norwalk virus, there are 180 genetically and chemically identical subunits in the capsid. The subunits are actually larger than those of the picornaviruses, but most of the extra size comes from a second, projecting domain that serves functions other than the construction of a closed shell. The size of the *shell domain* (S domain) in both cases is just about 200 residues, and the folded structure of the domain is again a jelly-roll β -barrel. The important feature of the packing of these 180 S domains is illustrated by the TBSV diagram in Figure 3.8. The contents of an icosahedral asymmetric unit can be described as three chemically identical subunits, with somewhat different conformations. These conformers are denoted A, B, and C, echoing the designation of commas in Figure 3.7. The differences among the conformers reside principally in an ordered or disordered conformation for part of the N-terminal arm and in the angle of the hinge between the S domain and the projecting, *P domain*. The A and B conformations are nearly identical, with disordered arms and similar hinge angles. The C conformation has an ordered arm and a different hinge angle from A and B. The ordered arms extend along the base of the S domain and intertwine with two others around the icosahedral threefold axis. Thus, the whole collection of 60 C-subunit arms forms a coherent inner scaffold.

How equivalent or nonequivalent are the actual inter-subunit contacts in TBSV and related structures? Most of the interfaces are well conserved, with very modest local distortions that do not significantly change the way individual amino acid side chains contact each other. The interfaces between conformers that do exhibit noteworthy differences are those that include the ordered arms in one of the quasiequivalent locations (the C-conformer). At these interfaces, there is a discrete switch between two states, with ordering and disordering of the arm as the toggle. Nonetheless, many side chain contacts are conserved around the fulcrum that relates an A/B dimer to a C/C dimer (Fig. 3.8).

Only certain multiples of 60 subunits can pack with quasiequivalent contacts; they are given by the formula $T = h^2 + hk + k^2$, where h and k are any integer or zero.¹²⁵ The multiple T is known as the *triangulation number*, because, as illustrated by comparison of the 60- and 180-comma structures in Figures 3.3 and 3.7, they correspond to subtriangulations of an icosahedral net on the surface of a sphere. Such nets are known as *surface lattices*. If we think of an icosahedrally symmetric structure as a folded-up hexagonal net (Fig. 3.9), then 12 uniformly spaced sixfold vertices are transformed into fivefold vertices.

FIGURE 3.8. Tomato bushy stunt virus (TBSV), a T = 3 icosahedral structure. **Top:** Modular organization of the TBSV coat-protein polypeptide chain. R: unstructured, positively charged N-terminal region. β , e: segments of the “arm,” ordered on the C-conformation subunits and unstructured on the A- and B-conformation subunits; when ordered, the β segment forms an interdigitated β -annulus with corresponding segments from two other chains, and the e segment extends along the base of the subunit (see panel at **bottom, left**). S: shell domain, a β -jelly-roll. P: projecting domain, a β -sandwich of somewhat different fold from the jelly-roll S domain. h: hinge between the S and P domains. The color coding in the bar representation of the chain is repeated in the ribbon diagrams of the C (**left**) and A/B (**right**) conformations. Note that the two conformations differ in two respects: the ordering of the arm and the hinge angle between S and P domains (curved arrows on the **right-hand ribbon diagram**). **Center:** Ribbon representation of the entire protein coat of the virus; the colors of the A-, B-, and C-conformation subunits are as in Figure 3.7. **Bottom left:** Schematic figure, showing that the arms of the C-subunits (green) interdigitate around threefold axes of the icosahedral symmetry, forming a coherent inner framework. **Bottom right:** Magnified view of some of the C-subunits from the coat seen in the central part of the figure, illustrating the β -annulus (β) and the extended part of the arm (e). In the **bottom center** are schematic views of the C-C and A-B dimers, showing how the hinge between S and P domains correlates with the ordering of the arms (inserted into the slot between S domains, which have rotated away from the contact that they have when the arms are unfolded into the particle interior).

FIGURE 3.9. Generation of curved structures from planar lattices. **A:** Portion of a hexagonal lattice. Six triangular cells of the lattice meet at each lattice point, and each triangular cell contains three “subunits” (commas). Thus, there is a sixfold symmetry axis at each lattice point, a threefold symmetry axis at the center of each triangle, and a twofold axis at the midpoint of each edge. Imagine that the lattice extends indefinitely in all directions. **B:** Curvature can be introduced by transforming one of the sixfold positions into a fivefold (**center**). A 60-degree “pie slice” has been removed from the object in **A** by cutting along the heavy dotted lines, and the cut edges have been joined to generate the curved lattice shown here. **C:** If further cuts are made at regular intervals in an extended lattice, such as the one in **A**, and the edges joined as in **B**, a closed solid can be produced. In the case of the icosahedral solid shown here, vertices of the lattice separated by two cell edges have been transformed into fivefolds, while the intervening lattice points have been left as local sixfolds, producing a $T = 4$ ($h = 2, k = 0$) structure. Notice that the local sixfolds are actually only approximately sixfold in character; they correspond strictly to the twofold axes of the icosahedral object. **D:** Lines joining the centers of the triangular cells in **A** create a pattern of hexagons. **E:** When a sixfold is transformed into a fivefold, a hexagon becomes a pentagon. **F:** If second nearest-neighbor lattice points are all transformed into pentagons, a soccer-ball figure results. This is a $T = 3$ structure. A description of the lattice as a network of hexagons and pentagons is complementary to its description as a network of triangles. The representations in Figures 3.3, 3.5, 3.13, and 3.16 (**left**) use triangles. The representation in Figure 3.16 (**right**) uses hexagons and pentagons. One representation for a given lattice can easily be derived from the other.

Nonequivalent Icosahedral Surface Packings

Hexagonal packing is an efficient way to tile a surface (think of hexagonal floor tiles), even if the building blocks themselves do not have sixfold symmetry and hence do not interact identically with their neighbors. In many larger, icosahedrally symmetric virus particles, the outer-shell building blocks are centered at the vertices of an icosahedral surface lattice, subtriangulated as anticipated by Caspar and Klug, but the oligomeric building blocks themselves are not hexamers. In some cases, for example, adenoviruses (Fig. 3.10), they are trimers, with a chemically distinct, pentameric building block on the fivefold vertices; in other cases, for example, the polyoma- and papillomaviruses, the building blocks are all identical pentamers (Fig. 3.1). Viewed at low resolution (e.g., by negative-stain electron microscopy), all of these viruses have globular “lumps” at the vertices of a lattice with one of the allowed triangulation numbers ($T = 25$ for the adenoviruses: Fig. 3.10; $T = 7$ for the polyoma- and papillomaviruses: Fig. 3.1), but when seen at higher resolution, the six-coordinated lumps are actually trimers or pentamers, and in the former case, the five-coordinated lumps are pentamers of a related but distinct polypeptide chain.

Special mechanisms (either involving other structural proteins or flexible intersubunit connections) are needed to hold the particle together because a single set of repeating, quasiequivalent intersubunit contacts is not possible. Before the molecular principles of virus structure were fully understood, the globular lumps seen by low-resolution electron microscopy were called *capsomeres*, meaning the *structural units* of the *capsid*. This word is still used when referring to apparent morphologic units on the surface of a virus shell, but it is best reserved for cases where all capsomeres are the same and hence represent a defined oligomer, as in the pentameric units of papovaviruses (see later).

The flaviviruses and picobirnaviruses illustrate yet another adaptation to icosahedral packing. As illustrated in Figure 3.7, the asymmetric unit of an icosahedral surface lattice can be represented by a (spherical) triangle with a fivefold axis and two adjacent threefold axes as its vertices. The flavivirus envelope protein (E) is a flat, elongated dimer; three such dimers neatly fill a twofold-related pair of asymmetric-unit triangles, with the dyad of the central dimer coincident with the icosahedral twofold (Fig. 3.11).¹²⁸ The shell contains 180 subunits, but not in a $T = 3$ arrangement. The picobirnavirus coat protein

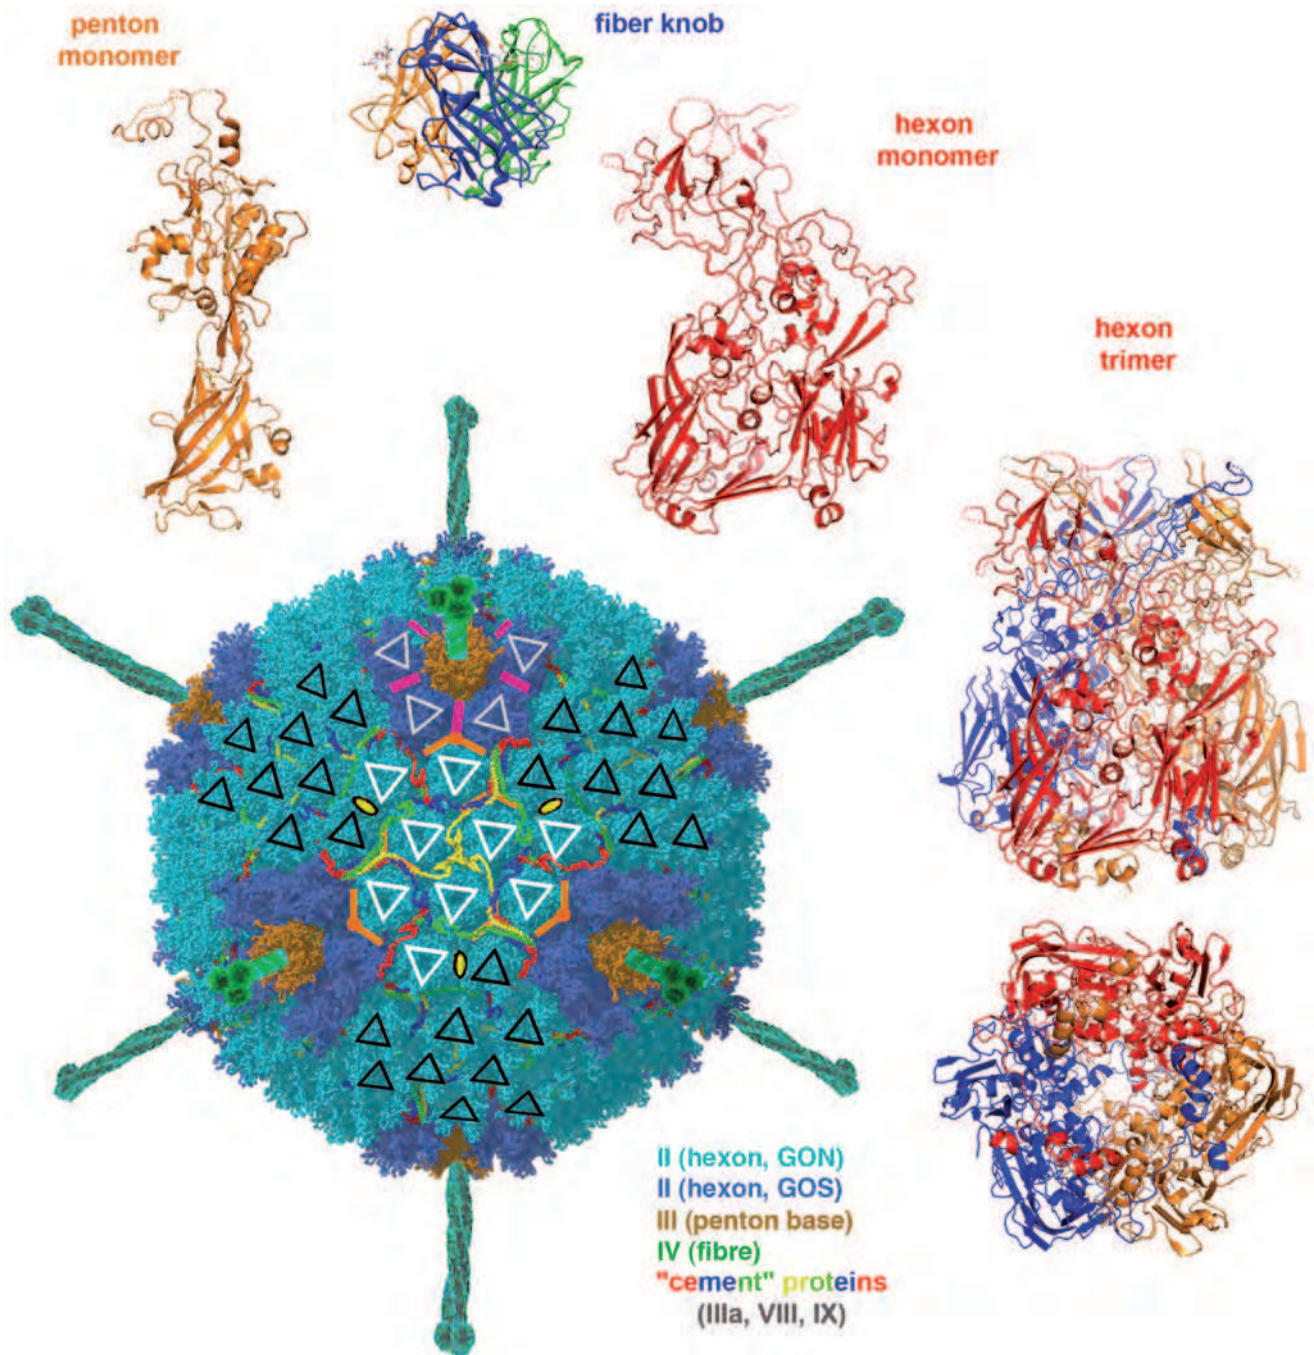

FIGURE 3.10. Adenovirus structure. A representation of the complete particle, based on a high-resolution electron cryomicroscopy (cryoEM) image reconstruction,¹⁴² is at the **lower left**, surrounded by ribbon representations of a number of the component proteins. The view of the particle is along a threefold symmetry axis. The hexons (light and medium blue) and the pentons (brown) lie on vertices of a $T = 25$ icosahedral lattice, but the hexons are actually trimers with a pseudohexameric character, as illustrated by the “bottom view” (as if from the particle interior) at the **lower right**. Three species of so-called cement proteins (IIIa, VIII, and IX) retain the hexons and pentons in the shell and determine its fixed geometry. One of them (various chains in red, dark blue, yellow, and light green) fits into the crevices between the hexons and organizes them into *groups of nine* (GON)—as shown by the sets of white and black triangles on the hexon surfaces. The other two are on the inner surface of the hexon–penton shell and cement five “peripentonal” hexons and the penton base into a *group of six* (GOS); locations of some of them are shown here simply as magenta and orange lines, because they are not visible from the outside of the particle. The trimeric fibers project from each penton base, with a receptor-binding knob (**top of figure**) at their tip. Each hexon monomer (see red ribbon diagram, **upper right**) has two jelly-roll β -barrels, in parallel orientation, imparting a pseudohexagonal character to the trimer. The penton base (**upper left**) has a single β -jelly roll. (Image reconstruction courtesy Z. H. Zhou; see also Harrison¹⁰³).

FIGURE 3.11. Organization of a flavivirus particle. Ninety dimers of the E protein tile the surface as shown. E is an elongated, three-domain protein (**lower left**), oriented with its long axis parallel to the surface of the virion. At the tip of domain II (yellow) is a hydrophobic *fusion loop* (orange, shown also as an asterisk on the larger schematic).

is so shaped that two dimers can fill a similar (smaller) rhombic unit; the icosahedral twofold lies between the two dimers, and the complete coat contains 120 subunits.⁶⁶ Recombinant brome mosaic virus coat-protein dimer, expressed in yeast cells, packs in a closely related way when it assembles into 120-subunit virus-like particles.¹²⁶

The arrangement of 120 copies of the inner- (core-) shell protein in double-stranded RNA (dsRNA) viruses is a particularly striking example of nonequivalent packing (Fig. 3.12). There are two completely distinct environments for this protein (designated A and B in Fig. 3.12, center): two is not a permitted triangulation number, and quasiequivalent packing of 120 proteins in an icosahedral array is not possible. The amino acid side chains on the lateral surface of the core-shell protein have different partners, depending on the interface in which they lie. The distortion of the subunit itself, when the two environments are compared, is quite small.

Frameworks and Scaffolds

The protein subunits of TBSV or picornaviruses have extended N- or C-terminal arms augmenting a central jelly-roll β -barrel. These arms are essential for building a stable coat. They form an internal framework, such as the one illustrated for TBSV in Figure 3.9. In TBSV, the *assembly unit*—the oligomer of the coat subunit that forms spontaneously in solution (and by inference, in the cell following its synthesis)—is a dimer, which can have two conformations: an “A/B” dimer, with disordered N-terminal arms, and a “C/C” dimer, with folded arms.¹⁰⁵ The local curvature of those two conformations is different, and the framework of C/C arms fixes the overall diameter of the particle. Removal of the N-terminal arms of TBSV-like subunits leads to self-assembly of a small, 60-subunit icosahedrally symmetric particle that cannot package RNA.⁸⁸ That is, without the arms, there is no mechanism for a conformational switch.

In the papilloma- and polyomaviruses, N- and C-terminal extensions (principally the latter) of the subunit globular

FIGURE 3.12. Molecular organization of a rotavirus particle, illustrating the multiple concentric protein shells.^{42,202,259} The complete virion (**top**) or *triple-layered particle* (TLP) has an outer layer composed of VP7 (yellow) and VP4 (red: cleaved during maturation into two parts, VP8* and VP5*, which remain associated). The *double-layered particle* or DLP (**bottom**) has a core shell (**center**) with 120 VP2 subunits (blue) surrounded by a layer of 290 VP6 trimers (green) in a $T = 13$ icosahedral lattice. The VP6 layer in turn dictates the organization of the VP7 layer, which clamps into place 60 VP4 trimers projecting from a particular set of six-coordinated positions. The locations of the VP1 polymerase (purple, ribbon representation)⁷² and of tightly wound, double-stranded RNA (dsRNA) (magenta)¹⁵¹ are also shown in the bottom cutaway. The icosahedrally symmetric core shell has 120 VP2 subunits in two sets (designated A and B, dark blue and light blue, respectively), with completely nonequivalent contacts and only slightly different conformations. This type of shell is characteristic of many groups of dsRNA viruses.

domains tie together the pentameric building blocks, which have almost no contacts except through these extensions (Fig. 3.13).^{139,246} Flexibility of the arms allows formation of the different kinds of contacts required to surround a pentamer with six other pentamers (i.e., to position a pentamer at the

FIGURE 3.13. Packing of pentamers in the capsids of polyoma- and papillomaviruses. The ribbon diagrams in the center show pentamers of VP1 (polyomaviruses) and L1 (papillomaviruses), viewed from their outward-facing surfaces. Note the C-terminal arms of the subunits, which extend away from the pentamers in VP1 but loop back to it in L1. The schematic diagrams to the left and right illustrate the packing of these pentamers in the virion shell. The framework shows a $T = 7$ icosahedral lattice; VP1 or L1 pentamers are centered on both six- and five-coordinated positions.

six- as well as at the five-coordinated vertices of a $T = 7$ subtriangulated icosahedral lattice). The C-terminal arms emanate from one pentamer and dock into another. The way they dock is the same for all 360 arms, with identical interactions locking them in place; their configurations differ, however, between the point at which they emerge from the globular domain of their subunit of origin and the point at which they dock into their target subunit.

Larger and more complex structures, such as adenoviruses, have separate framework proteins. The principal outer-shell components of adenoviruses are *hexons* (trimers of a subunit with two similar jelly-roll β -barrel domains) and *pentons* (pentamers of a subunit with a single jelly-roll β -barrel domain); a set of additional proteins cement the structure together and determine its size (Fig. 3.10).^{80,214,215} The elaborate interaction patterns of these *cement* proteins stabilize a *group of nine* hexons, centered on the icosahedral threefold axis, and a *group of six* (five hexons and a penton), centered on the icosahedral fivefold axis.^{134,142} The structure of an adenovirus-like bacteriophage, PRD1,¹⁶ shows a somewhat simpler size-determining and stabilizing framework: a *tape-measure protein* extends from the penton toward the icosahedral twofold axis, where it interacts with an identical protein running toward it from the twofold-related penton (Fig. 3.14).² Unlike adenoviruses, PRD1 has a lipid-bilayer membrane between the P3 layer and the internally coiled DNA.^{11,49}

During assembly of the heads of most double-stranded DNA (dsDNA) bacteriophages, an internal scaffold protein directs formation of a *prohead*.³³ Signals related to initiation of DNA packaging trigger release and recycling (P22) or degradation (T4) of the scaffold, accompanied by a reorganization and expansion of the head (Fig. 3.15A,B).^{68,119} DNA is pumped into the empty head until it reaches a tightly coiled state, as illustrated in Figure 3.15C.^{69,70,211} In these examples, *scaffold* is a good description of the internal protein, because it is removed once the structure is complete.

The fundamental principle embodied in all the various structures just described is one of mass production. One or more standard building blocks assemble into the larger structure. In simple ($T = 1$) cases, such as the parvoviruses and picornaviruses, a repeating set of identical interactions determines the final structure. Even in many of these cases, however, extended arms form an interconnecting framework. In more elaborate cases, framework elements, either permanent or transient, ensure a unique outcome.

Elongated Shells

The examples in Figure 3.16 illustrate elongated particles with caps at either end. In many of the dsDNA bacteriophages, the shell looks like a familiar icosahedral design at the poles. As the lattice approaches the equator, however, the regular interspersion of fivefolds and local sixfolds gives way to local sixfolds only, so that there is a tubular region around the middle of the particle (Fig. 3.16A–C).²²⁴ The tubular region can be of varying extent; in extreme cases, it can be much longer than the caps themselves. A further variation on this theme is found in the shells formed by the CA fragment of the lentivirus Gag protein. Conical structures seen within HIV-1 particles have been shown to be based on the sort of arrangement shown in Figure 3.16D, where one cap has more than six fivefolds and the other has less, so that the diameters of the two caps are different.⁸³ (Note that if there are only sixfold and fivefold vertices in a closed surface lattice, there will always be exactly 12 of the latter.)

Multishelled Particles

Most dsRNA viruses have a genuinely multishelled icosahedral organization, with some common features and some variation from group to group (see Chapters 44–46). In virions of the mammalian dsRNA virus groups (reoviruses, rotaviruses, and orbiviruses), the innermost protein shell contains 120 copies of

FIGURE 3.14. Bacteriophage PRD1. **Left:** Side and bottom views of the *hexon* protein, P3. The colors correspond to those in the ribbon diagrams of the adenovirus hexon trimer in Figure 3.10. Like the adenovirus hexon, P3 has two jelly-roll β -barrels, but the loops that project outward are much less elaborate.¹⁶ (The variable adenovirus hexon loops probably evolved as a means of immune evasion, not relevant for a bacteriophage.) The image on the **upper right**, based on a crystal structure of the intact phage particle,² is a view along a twofold axis. One three-fold set of P3 trimers is highlighted by triangles. The pentons (P31) are in red. At the **lower right** is a view with the outer layer stripped away, to show the extended *tape-measure* protein, P30, which helps determine the size of the shell, and the lipid bilayer just beneath it. There are 60 copies of P30; each chain extends from a twofold axis (N-terminal end, blue) to the inner surface of a penton (C-terminal end, red). At the twofold axis, one P30 associates with a second, twofold-related P30, which projects toward the opposite icosahedral vertex. (Courtesy D. Stuart, Oxford University.)

FIGURE 3.15. Capsid reorganization and DNA packaging in tailed bacteriophages.¹¹⁹ **A:** Surface of the HK97 procapsid. The surface organization is a locally distorted $T = 7$ arrangement, with fivefold symmetric association of the subunit at the fivefold positions (beige) but a skewed arrangement in the rings of six subunits that surround a local six-coordinated position (colored in magenta, blue, red, green, yellow, and cyan, in clockwise order).⁵³ An N-terminal extension of the head subunit is the scaffold for prohead assembly; its cleavage by a co-assembled protease triggers rearrangement of the subunits into the expanded, thinner, more angular shell illustrated in **B**.⁶⁵ **B:** Capsid (head) of the mature HK97 particle; molecular surface, based on crystallographic model, colored as in **A**.²⁴² This view is oriented so that a fivefold axis is vertical. The image is derived from the structure of an empty capsid with 420 subunits in a $T = 7$ icosahedral lattice. In a wild-type bacteriophage particle, one of the rings of five subunits is replaced with a portal protein connected to a tail (see **E**). **C:** Expanded view in ribbon representation of one icosahedral asymmetric unit (i.e., one of the five subunits in the pentameric ring and one each of the quasisymmetric subunits in the hexameric ring). All subunits are chemically identical. In HK97, but not in many related bacteriophages, an intersubunit isopeptide bond, which forms during maturation, crosslinks the entire coat.⁶⁵ **D:** A further enlarged view of a single, 31-kD subunit. The 105-residue N-terminal extension that functions as an assembly scaffold is indicated schematically by a dotted line. **E:** Cutaway representation of a three-dimensional electron cryomicroscopy (cryoEM) image reconstruction of bacteriophage P22. Its assembly is formally similar to that of HK97, but there is a distinct, recycled scaffold protein³³ and no covalent crosslinking of the head.¹⁷³ The packaged DNA (green) winds tightly around an internal extension of the portal protein (red).^{169,222} The axis of DNA winding is vertical in this view; averaging of many particles in the reconstruction produces concentric shells of density, because the exact register of the DNA coils varies from particle to particle. (Images in **A–D** from Vlrus Particle Explorer [VIPERdb] Web Site, <http://viperd.b.scripps.edu/>.)

FIGURE 3.16. Elongated shells. A–C: Bacteriophage $\phi 29$.²²⁴ The surface lattice of the $\phi 29$ capsid (**A**) has the equivalent of a $T = 3$ icosahedral cap (**B**) at either pole with an equatorial insertion of two rows of six-coordinated positions (i.e., six, locally sixfold-related, coat-protein subunits). The blue dots are at five-coordinated positions (five, locally fivefold-related, coat-protein subunits); the red dots are at the six-coordinated positions of a $T = 3$ lattice in the cap; the orange dots are at the inserted six-coordinated positions. The cap at the “south pole” is further modified by replacement of the axial pentameric cluster of coat subunits with the collar and tail structure, as shown in the surface view in **C**. **D:** The conical structure of the mature capsid of HIV-1.⁸³ The capsid subunit, CA, cleaved from the Gag precursor, forms a structure with two unequal caps, one with seven five-coordinated positions and one with five. In the former, the five-coordinated positions have more intervening six-coordinated lattice points than in the latter, so that the radius of the one is larger than the radius of the other. The shaft of six-coordinated positions is wrapped in such a way that a circumference includes increasing numbers of subunits as one traces from the “bottom” to the “top” of the conical capsid, as illustrated here. The two caps have a five-coordinated lattice point at the apex, but immediately deviate from an icosahedral arrangement, as shown in the end-on view of the lower cap (**bottom left**).

a large, rather plate-like protein^{96,151,186} (Fig. 3.12). Surrounding the inner shell is a second characteristic layer. In most cases, it contains 780 copies of a trimeric protein with a radially directed jelly-roll β -barrel and inwardly directed N- and C-termini, which together form an extensive and largely α -helical “base” domain.^{95,140,149} This second layer corresponds closely to a “classical,” quasiequivalently packed, $T = 13$ icosahedral shell—all the interactions between adjacent trimers are variations on the same set of contacts.

Various elaborations and simplifications of the two-layer design just described differentiate the families of dsRNA viruses. For example, in the reoviruses, the $T = 13$ layer has gaps, through which pentameric “turrets” of yet another protein, anchored on the inner shell, project; only 600 of the potential 780 subunits are actually present.^{27,64,186} The birnaviruses lack the 120-subunit layer altogether and have instead 780 copies of a single major capsid protein, with a shell domain that resembles those of plant and insect viruses and a trimer-clustered projecting domain that resembles the jelly-roll β -barrel in the $T = 13$ shell of rotaviruses and orbiviruses.⁵⁴ The $T = 13$ packing of the shell domain so closely recalls that of its counterparts in $T = 3$ and $T = 4$ positive-strand RNA virus structures that a bridge between the two families seems plausible. Similarities in the RNA-dependent RNA polymerases of these viruses also suggest some common ancestry. The dsRNA bacteriophages such as $\phi 6$ contain the 120-subunit, inner-shell

layer and a fenestrated, $T = 13$ layer (rather like reoviruses), contained within a lipid-bilayer membrane.^{27,112,114,236}

Rearrangements in Surface Lattices

Icosahedral surface lattices can undergo rearrangements, which preserve the overall symmetry of the structure but change the pattern of specific intersubunit contacts. There can be an accompanying change in the diameter of the shell. These rearrangements are cooperative—that is, they occur more or less simultaneously across the whole structure. As illustrated in Figure 3.14, when dsDNA bacteriophages such as P22 insert their genomic DNA into a preformed prohead, the outer shell of the prohead expands as its subunits shift around to form the mature structure.^{33,53,117,133} Another well-characterized example is expansion of the $T = 3$ plant viruses, which occurs when the calcium ions that stabilize a particular set of subunit interfaces are removed¹⁹⁰ (Fig. 3.17). This swelling is believed to be the first step in disassembly; plant viruses are injected by their vectors directly into the cytoplasm of the recipient cell, where they are exposed to a low Ca^{2+} environment. A similar, but transient, expansion occurs when poliovirus binds its receptor.¹⁵ In both the $T = 3$ plant viruses and the picornaviruses, internally directed “arms” of the protein subunits move outward from the interior as expansion creates gaps in the shell. Exposure of the arms may be part of the uncoating process in the case of the plant viruses or of the penetration

FIGURE 3.17. Expansion of tomato bushy stunt virus (TBSV).¹⁹⁰ The mature, compact particle (**upper left**) expands when Ca^{2+} ions (small circles) are removed. The expanded form (**upper right**) is reached by a smooth transition, in which many of the intersubunit contacts are conserved. The contacts that included the ions in the compact state have separated substantially, creating a fenestrated shell.

process in the case of the picornaviruses. Cooperativity of these rearrangements implies that a few points of inhibition can prevent the change. For example, only a few intersubunit crosslinks from bound neutralizing antibodies are sufficient to block infection by a picornavirus particle.⁷¹ The same may be true of small molecules that inhibit the subunit conformational changes needed for the receptor-triggered expansion of picornaviruses.^{8,177,212}

Helical surface lattices can also rearrange without dissociating. Contraction of bacteriophage tail sheaths is a good example.

Two Recurring Globular Domains in Icosahedral Capsid Proteins

The icosahedrally symmetric shells of nearly all well-characterized, nonenveloped viruses contain one of two types of globular domain. (The known exceptions at the time of writing this chapter are the RNA bacteriophages—R17, Q β , and their relatives²²⁹—and the dsRNA picobirnaviruses.⁶⁶) One is the jelly-roll β -barrel in viruses of animals and plants, which we have described in various examples of viruses of animals and plants; it is also the principal component of icosahedral ssDNA bacteriophage capsids (e.g., ϕ X174).¹⁵² The various ways this module can form a coat are quite different, of course, and we have emphasized earlier the importance of framework components (either as extensions of the polypeptide chain of the β -barrel or as separate protein species) in directing or regulating coat assembly. What sort of evolutionary parsimony resulted in such widespread appearance of a single kind of protein module is not evident. Viruses can jump from plants to insects and from insects to vertebrates, so the recurrence of the jelly-roll β -barrel is unlikely to reflect a common origin for all these viruses that antedates host divergence, but rather the result of more recent selection and genetic exchange. Cellular fusion proteins acquired from viral fusion proteins through retrotransposons illustrate one way in which such exchange can occur.

Figure 3.14 shows the second basic building block, discovered initially in the coat of dsDNA bacteriophages such as HK97 and subsequently found in most other dsDNA bacteriophages (T4, lambda, P22, etc.). This *HK97 fold* is also the core of the herpesvirus capsid subunit.⁹ Like their bacteriophage cousins, herpesviruses pump their genome DNA into a preformed shell through a specialized icosahedral

vertex and a dodecameric *portal protein*.^{39,163,164} Adenoviruses, and probably their bacteriophage cousins like PRD1, with hexon-like capsid subunits, are also thought to insert DNA into a preassembled empty capsid, but the motors that effect the insertion seem to be different from those in the herpesviruses.^{113,170,256,257} Thus, the structures of the coat proteins of two major classes of dsDNA viruses appear to correlate with the machinery by which members of each of these classes package DNA.

SELF-ASSEMBLY AND CLEAVAGE STEPS

Some of the simplest virus particles can assemble spontaneously from their dissociated or recombinant components, in the absence of any further modifications or scaffolds. These particles are said to *self-assemble*, because they do not require additional activities (encoded either by the virus or by the host cell) to form. In an infected cell, however, host chaperones, such as Hsc70 and its paralogs, may enhance efficiency of subunit folding or subunit assembly, even when they are not absolutely essential.

Most viruses, and nearly all viruses that infect animal cells, cannot reassemble from dissociated particles, because one or more irreversible steps intervene in forming the mature, infectious virion. The picornaviruses, already described, illustrate one kind of irreversible step. In an infected cell, the principal structural proteins are cleaved from a polyprotein precursor (by a viral protease) before particle assembly, but one final, autocatalytic cleavage step occurs after assembly—the scission of a peptide bond between VP4 and VP2 (see Chapter 16 and caption to Fig. 3.7). The cleavage depends on the three-dimensional arrangement of the scissile bond, as found in a newly assembled precursor particle. Rearrangements of parts of the subunits following the cleavage stabilize the now mature, infectious virion. Proteolytic cleavages by cellular or extracellular host proteases are critical steps in the maturation of many types of virus particles, even when processing of a precursor polyprotein is not involved. For example, many of the surface glycoproteins that facilitate membrane fusion during entry of enveloped viruses require activation by a furin-like protease late in the secretory pathway.

Specific, postassembly proteolytic cleavage usually has two consequences. First, as in poliovirus or many viral fusion

proteins (see later), it leads to a local rearrangement of polypeptide chains that stabilizes the structure. Second, it allows the structure to undergo a much larger reorganization when “triggered” by binding of a specific ligand. Thus, when a mature poliovirus particle binds its receptor, an expansion occurs that allows VP4 to escape and to interact with adjacent membrane—a critical first step for translocating the particle (or its genome) from an endocytic compartment into the cytosol.^{21,100,157} Likewise, many fusion proteins of enveloped viruses undergo large-scale, fusion-promoting conformational changes when they bind protons in acidic endosomes—but again, only if the critical cleavage has occurred.²⁰⁹ In physicochemical terms, the cleaved structure is *metastable*: a large kinetic barrier separates it from its true energy minimum. The barrier can be so large that the virus remains infectious for many weeks or months. Ligand binding (receptors, protons, etc.) lowers the kinetic barrier, leading to a rapid conformational rearrangement, coupled in most cases to an important step in viral entry.

GENOME PACKAGING

Incorporation of viral nucleic acid must be specific, but it must also be independent of most of the base sequence of the genome. Therefore, viral genomes generally have a *packaging signal*—a short sequence or set of sequences that directs encapsidation. Recognition of the packaging signal depends on the nature of the genome and on the complexity of the assembly mechanism. In many cases, there is a direct interaction between the packaging signal and the capsid protein. Some complex viruses insert genomic nucleic acid into a preformed shell, and genome recognition is a property of the packaging system. If replication and packaging are closely coupled, as they are in picornaviruses,¹⁶⁸ flaviviruses,¹²¹ and at least some RNA plant viruses,⁵ a specific packaging signal may be less essential.

Positive-Strand RNA Genomes

Viruses with ssRNA genomes (e.g., most icosahedral plant viruses; picornaviruses; alphaviruses; flaviviruses) require no definite overall secondary or tertiary fold for the genomic RNA, aside from the restriction that it fit within the shell. This restriction is actually quite severe, and the RNA is packed very tightly, approximating the density of RNA in crystals.¹⁶⁰ Even random-sequence RNA contains about 60% to 70% of its nucleotides in base-paired stems,⁹¹ and to fit efficiently within the interior of a capsid, these RNA stems must pack tangentially, not radially, with many of the stems in contact with the inward-facing surface of the shell. Such packing can be achieved by assembly around the RNA, without definite capsid–RNA interactions, other than those of a few subunits with a packaging signal (if present). In some viruses, segments of partially ordered RNA can be detected, tucked into shallow grooves on the inner capsid surface.^{44,74} The ordered positions of these segments probably result just from the shapes of the grooves and the possible structures that a tightly packed polynucleotide chain can adopt; there do not appear to be any base-specific contacts.

In a few cases, we know the molecular details of RNA packaging-signal recognition. A translational regulatory sequence

that is probably also the packaging signal of RNA bacteriophages such as MS2 and R17 folds into a stem-loop structure (Fig. 3.18A), recognized by a dimer of the coat protein (the assembly unit for this T = 3 particle).^{30,230,231} Bases in the loop and a looped-out base in the stem fit into a groove on the inward-facing surface of the subunit dimer; conserved bases make defined protein contacts.

Many nonenveloped, positive-stranded RNA viruses of eukaryotes recognize their genomic RNA, not through a groove-like site on the protein, but rather through a flexibly extended, positively charged protein arm, often at the N-terminus of the coat protein. There is an interaction of this kind between the coat protein of alfalfa mosaic virus and a 3′-terminal segment of RNA.⁹⁹ A bound coat-protein dimer is essential for replication—probably to recruit the RNA-dependent RNA polymerase. The same interaction is also likely to initiate packaging. The dimer contacts a pair of tandem RNA hairpins through a 26-residue, N-terminal arm. The two arms and the two RNA stem loops fold together into a well-defined structure, cross-strutted by base pairing between conserved AUCG sequences that follow each stem (Fig. 3.18B). There are six such stem loops in the 3′ segment of the viral genome; it is possible that binding of three coat-protein dimers initiates shell assembly.

The enveloped alphaviruses also have a multi-stem-loop packaging signal, recognized (with structural details not yet determined) by an extended N-terminal arm of the nucleocapsid subunit.¹²² There appears to be some redundancy in the stem loops, all of which contain a GGG trinucleotide in the loop, as deletion of several of the eight stem loops does not compromise the efficiency of RNA packaging and virion assembly.

Retroviral packaging signals, known as *psi* sequences, are recognized by the nucleocapsid (NC) domain of the Gag protein. The HIV-1 *psi* element has a stem-loop structure that associates with two *zinc-knuckle* modules in HIV-1 NC⁶⁰ (Fig. 3.18C). The two zinc modules are flexibly linked in unbound NC, but they adopt a defined, three-dimensional organization in complex with the RNA. Thus, the structure of the RNA imparts additional order to the protein element with which it binds (just as in alfalfa mosaic virus).

Assembly of helical structures requires unwinding of any base-paired stems in the RNA genome being packaged. TMV has evolved an assembly-driven helix-breaking feature into its packaging pathway. Viral assembly begins at an internal origin sequence, about 1 kb from the 3′ end of the genome.^{227,261} A 75-base sequence containing a presumptive stem-loop structure is sufficient to initiate specific encapsidation (Fig. 3.18D), which proceeds by a mechanism that requires the 5′ end of the RNA to be drawn through a channel along the axis of the assembling particle.²⁸

The mechanism of overall condensation of a viral genome is in general distinct from the specific recognition just discussed, unless, as in TMV, there is a regular, repeated interaction between coat protein and genomic RNA. There are various strategies for neutralizing the net negative charge on the nucleic acid. Those icosahedral viruses with inwardly projecting, positively charged arms use most of their arms for nonspecific interactions with RNA and only a few for specific recognition. In the picornaviruses, polyamines are incorporated to achieve charge neutralization.

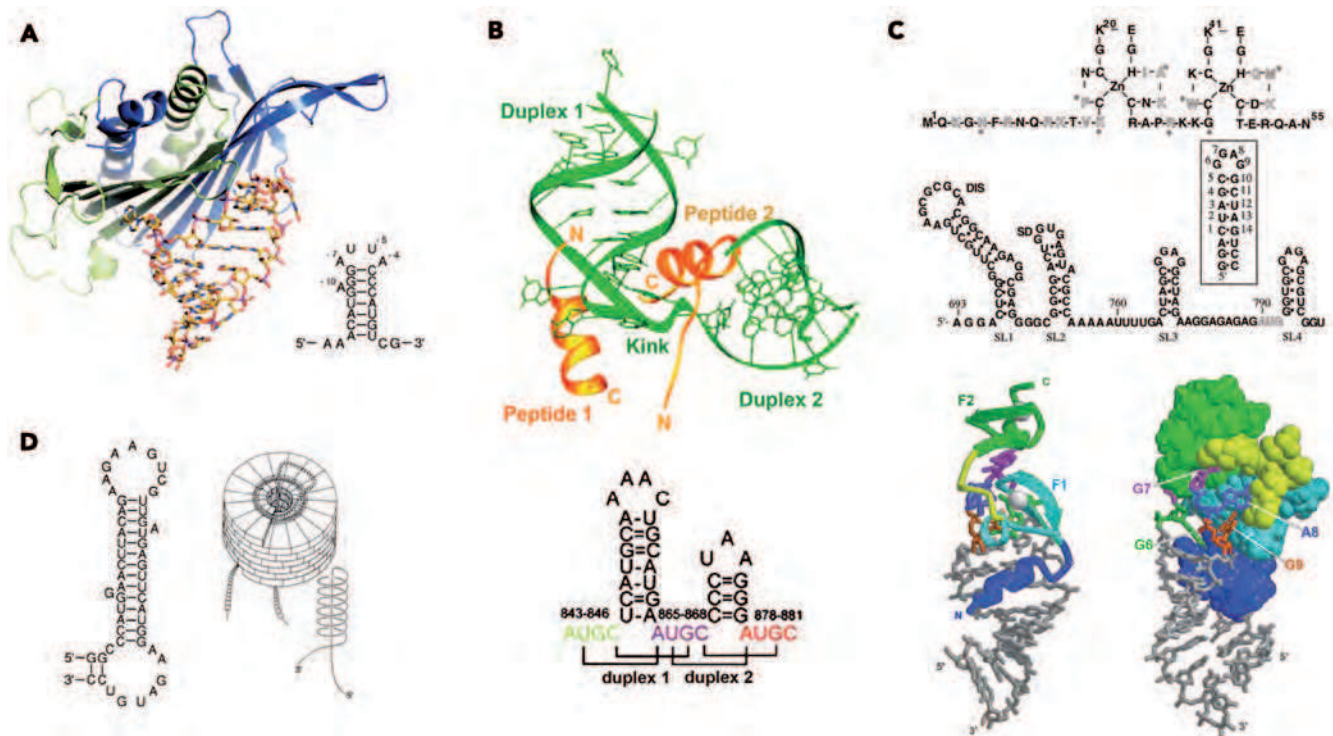

FIGURE 3.18. Various modes of single-stranded RNA (ssRNA) recognition and packaging. **A:** RNA bacteriophage. A stem-loop (sequence shown as inset) packs against the inward-facing surface of a protein-subunit dimer; there are specific contacts between residues in the protein and four unpaired bases (-4, -5, -7, -10). **B:** Alfalfa mosaic virus. A folded, stem-loop, RNA structure (green) is a docking site for two N-terminal subunit arms (gold). The arms are unstructured until they associate with the RNA. **C:** HIV-1. Two zinc-knuckle domains (labeled F1 and F2 in the ribbon representation at the lower left), near the C-terminal end of the Gag polyprotein (sequences shown at the top), bind a stem-loop structure in the packaging signal of the genomic RNA (center and bottom). Purine bases that have conserved stacking interactions are labeled in the surface representation at the lower right. **D:** Tobacco mosaic virus.^{28,227,261} The sequence at which RNA packaging initiates, shown on the left, is roughly 500 nucleotides from the 3' end of the genome, and assembly of the helical particle proceeds by addition of subunits at one end of the growing helix, drawing the 5' end up through the center of the particle, as shown on the right. Coating of the 3' overhang proceeds more slowly at the other end of the particle. (A adapted from Valegard K, Murray JB, Stonehouse NJ, et al. dsDNA Genomes

The best-understood dsDNA packaging mechanisms are those of the tailed bacteriophages.⁹⁷ DNA inserts into a preformed prohead, from which the scaffold has been lost by triggered release or by proteolysis.^{14,33} Removal of the scaffold leads in most cases to a substantial expansion of the head, accomplished through conformational rearrangements in the major capsid protein.^{68,119} The head itself is either an isometric icosahedral shell (e.g., lambda, P22, or HK97; Fig. 3.15) or a prolate one (e.g., T4 or ϕ 29; Fig. 3.16). In the latter cases, the scaffold protein directs the elongation. DNA packaging depends on adenosine triphosphatase (ATP) hydrolysis by a multicomponent motor. The *connector* or *portal protein*, which connects head to tail in the completed particle, is part of the motor complex, but the ATPase itself is shed from the prohead after DNA packaging is complete.⁹⁷ The ϕ 29 connector is a dodecameric ring attached at a fivefold symmetric vertex.²⁰⁷ The substantial

internal pressure of the packaged DNA²¹¹ may help drive injection into a target bacterium.

Various models have been proposed for the coupling of ATP hydrolysis by the five ATPase subunits that surround the connector with the concomitant transport of DNA into the head.^{1,156,207,217–219} To avoid entanglement, it is possible that the leading end of the DNA attaches to the head interior.¹⁰⁴ In P22, a tube-like, inward-projecting extension of the portal may also help direct coiling and prevent tangles²²²; closely related viruses lack the prominent tube, however. DNA insertion leads to formation of a tight, uniform coil (Fig. 3.15C). Because the DNA is tightly wound, the side-to-side spacing of adjacent segments is very regular; the value of this spacing is determined by the precise volume of the head and by the length of the inserted genome.⁶⁹ Viruses such as bacteriophage lambda that replicate their DNA in a rolling-circle mode couple DNA packaging with cleavage of the replicated concatemer. Others, such as

φ29, have a virally encoded protein that primes synthesis of both DNA strands and that remains attached to the ends of the encapsidated genome.

DNA packaging into herpesvirus capsids resembles the process just described for the tailed bacteriophages (see Chapter 75). Not only does the shell-forming domain of the major capsid protein appear to have the HK97 fold,⁹ as described earlier, but also the portal protein, attached to a unique vertex, likewise resembles its tailed-phage counterpart.^{113,164} Rolling-circle DNA replication late in infection yields a concatemer, and cleavage of the DNA into a single “head-full” accompanies encapsidation.

Adenoviruses have, near the left-hand end of their linear genome, a set of AT-rich repeats that determines DNA incorporation into virions (see Chapter 55). Virions contain about 1,000 copies of a protein (VII) with strong positive charge, and it is believed that this protein condenses the viral DNA within the virion core and that it may remain associated with the DNA after uncoating. In the adenovirus-like bacteriophage PRD1, there is a unique vertex defined by the presence of proteins required for DNA packaging and injection.⁹⁰ One of these, the ATPase, is distantly related to protein IVa2 of adenoviruses and more closely related to candidate packaging ATPases for other dsDNA viruses with internal membranes.¹¹⁵

Papovaviruses incorporate cellular histones, so that the closed, circular DNA comprises about 20 to 25 nucleosomes (see Chapters 53 and 54). This minichromosome is further condensed as the capsid assembles around it. Packaging appears to be directed by sequences in a histone-free region.

dsRNA Genomes

RNA packaging by dsRNA viruses presents several puzzles, the most important of which is selection of RNA segments (see Chapters 44–46). Reoviruses have 10 RNA segments, and rotaviruses, 11. Random incorporation would lead to a vanishingly small proportion of fully infectious particles. Moreover, the range of segment sizes is substantial, and a capsid-full of RNA accommodates just one of each size. The RNA must wind tightly into nonentangled spools to enable the many rounds of transcription of each gene segment that occur when the inner capsid particle is released into the cytoplasm of an infected cell.²²³

Some molecular details of assembly have been worked out for the dsRNA bacteriophage, φ6, and its relatives.^{153,180} A procapsid assembles, into which each of the three positive-stranded RNA segments inserts sequentially, in a specific order. Minus-strand synthesis occurs inside the shell. The procapsid includes the major shell protein (similar to that of reovirus or rotavirus, Fig. 3.12), the polymerase, an ATPase, and a protein thought to serve as an assembly “clamp.” One copy of the hexameric ATPase, which may be a packaging helicase analogous in function to the packaging proteins of dsDNA bacteriophages, lies at each fivefold vertex⁶¹; RNA insertion appears to occur at only 1 of these 12 positions, even though all are occupied by an ATPase.

Assembly of other dsRNA viruses probably exhibits some similar features, but it seems likely that the inner shell co-assembles with the polymerase and the various plus-strand RNA segments.¹⁷⁵ The rotavirus polymerase, VP1, recognizes a conserved sequence at the 3′ end of the plus strand (the template for dsRNA synthesis); this interaction may direct specific

packaging of viral RNA.¹⁴⁶ VP1 requires association with the shell protein, VP2, for activity, and it is plausible to infer that one copy of VP1 and 10 copies of VP2 (together with one copy of the capping enzyme, VP3) make up the inner-core assembly unit. The ssRNA template could extend away from the incomplete particle, with dsRNA synthesis as the driving force to reel it into the shell,^{82,151,174} or it could condense into the interior of the assembling shell, as in the ssRNA viruses. Packaging of the genome as ssRNA, rather than as completed dsRNA segments, has an attractive feature: the tightly wound dsRNA spools required to fit the full genome into the shell could be generated readily during synthesis²²³ (Fig. 3.12). The presence of an RNA cap-binding site on the surface of the polymerase provides a mechanism for associating a particular polymerase molecule with a particular gene segment during subsequent rounds of transcription, which occurs without disassembly.²²³

Reoviruses and rotaviruses have a nonstructural protein, designated σNS and NSP2, respectively, that appears to have a role in RNA packaging. NSP2 is an octamer with a central channel that could accommodate ssRNA.^{116,118,129,225} A second nonstructural protein, NSP5, appears to compete with RNA for binding to NSP2, suggesting it may have some sort of co-chaperone-like activity.¹¹⁸

The central question remains: how does packaging of the *n*th RNA segment lead to selection of segment *n* + 1? The most likely mechanism involves RNA–RNA recognition: for example, when the *n*th RNA has been partially packaged, a single-strand region near its trailing edge will be exposed and perhaps unwound from internal secondary structural interactions with regions already packaged. This trailing segment could then recognize some feature—base sequence or three-dimensional structure—of segment *n* + 1. An allosteric mechanism involving protein conformational changes has been proposed for packaging the three segments of φ6,¹⁵³ but extending such a picture to 10 or 11 distinct states seems unlikely.

Negative-Strand RNA Genomes

The nucleocapsid proteins (N) of three negative-strand RNA viruses with single-segment genomes (VSV and rabies virus, both rhabdoviruses, and borna disease virus) all have closely related structures.^{4,93,197} Recombinant N proteins from VSV and rabies viruses bind nonspecific RNA from the expression host and form rings of 10 to 14 subunits, with an N-terminal arm that embraces one neighbor in the ring and a loop near the C-terminus that extends into the other neighbor. The subunits have two lobes with a groove between them that faces the center of the ring and binds the RNA—nine bases per subunit. The VSV-N ring is evidently a more tightly wound and circularized version of the helical ramp that the nucleocapsid forms in the bullet-shaped rhabdoviruses (see Fig. 3.19). Sequences at the 5′ end of the negative-strand RNA, not present in the crystal structures, participate in specific packaging, but the structures do not indicate any preferential base recognition in the RNA grooves. One possibility is that there are distinct recognition events at the 5′ end, which can contact the lateral surface of the initial N-protein subunit in the ribonucleoprotein complex (RNP), and at the 3′ end, for polymerase entry.⁴ The polymerase must withdraw the RNA from the groove in the RNP.^{4,93}

Influenza, like other orthomyxoviruses, has an eight-segment genome. The eight RNPs resemble rods folded back on themselves and coiled.⁵¹ The rod lengths, from 300 to 1,200 Å,

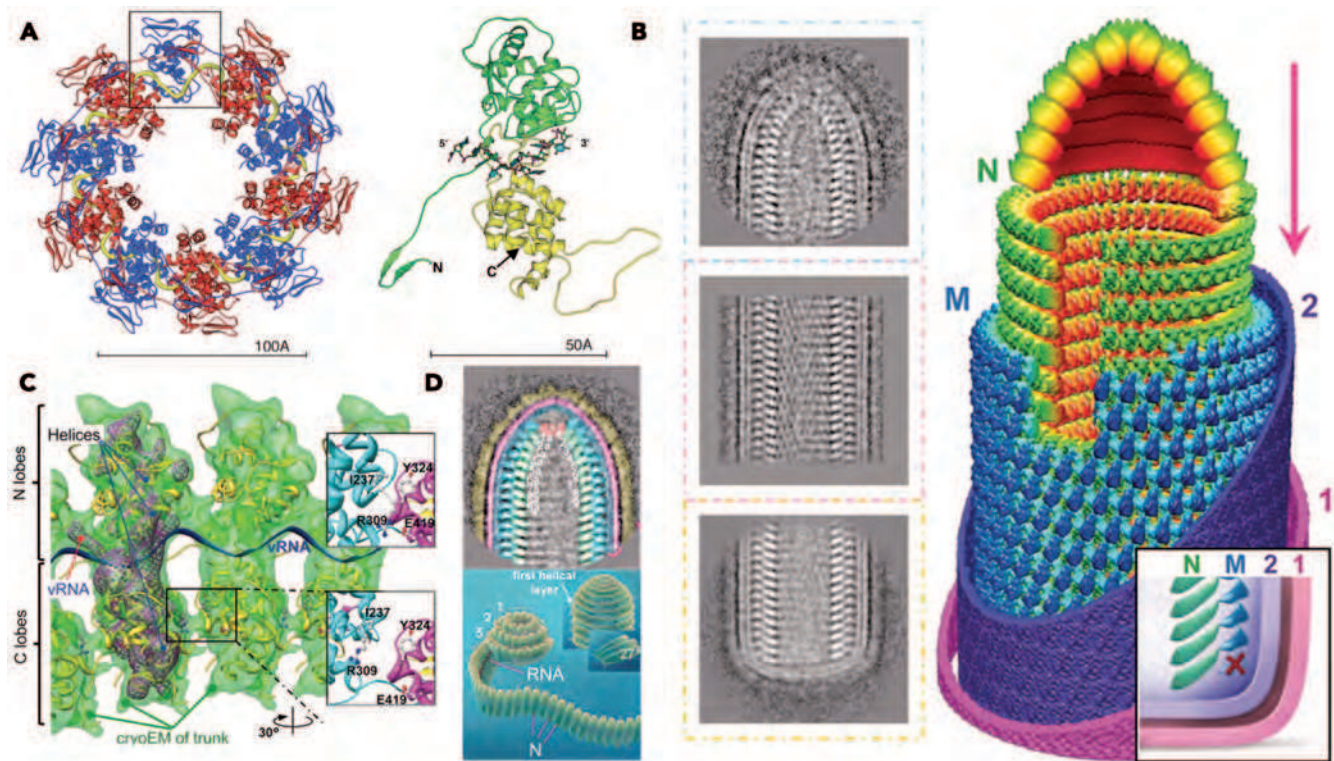

FIGURE 3.19. RNA binding and organization of the ribonucleoprotein complex (RNP) in vesicular stomatitis virus. A: Binding of RNA by N. **Left:** A ring of 10 recombinant nucleocapsid (N) protein subunits (alternating red and blue) binds a 90-nucleotide RNA segment (yellow). Recombinant N forms rings of various sizes, which take up random fragments of cellular RNA tightly enough to withstand purification. The view of the ring is from the “bottom” (C-terminal lobe) of the subunit; this lobe has been removed from one of the subunits (boxed), to show the (yellow) RNA more clearly. **Right:** One subunit from the ring, with a nine-nucleotide RNA segment in the groove between the two lobes of the protein. N- and C-terminal extensions project laterally and interact with neighboring subunits: the radius of the ring can vary, because these links are flexible. **B:** Image reconstruction, from electron cryomicroscopy (cryoEM) images (averaged projections of which are shown on the **left**), of the bullet-shaped vesicular stomatitis virus (VSV) particle. The outer glycoprotein (G) layer is not well-enough ordered to appear as discrete density in the map, but a fuzzy “halo” on the surface of the particle is evident in the projections. The nucleocapsid (green) winds into a shallow helix, guided by association with the matrix protein (M, blue), which in turn contacts the membrane (purple and magenta for the inner and outer headgroup layers, respectively). **C:** View from the inside of the RNP helix. The two insets illustrate the relationship between the subunits seen from the inside of the 10-subunit ring (**upper box**) and as they “unwrap” to form the larger-diameter helix in the virion (**lower box**). **D:** Color-coded interpretation of the upper projection in **B**, with colors as in the surface representation in **B**, and diagram showing wrapping of the RNP into the particle. The inner diameter of the helical coil formed by the RNP is about 450 Å and the rise per turn, about 50 Å. (**A** adapted from Green TJ, Zhang X, Wertz GW, et al. Structure of the vesicular stomatitis virus nucleoprotein-RNA complex. *Science* 2006;313:357–360. **B–D** adapted from Ge P, Tsao J, Schein S, et al. Cryo-EM model of the bullet-shaped vesicular stomatitis virus. *Science* 2010;327:689–693.)

correspond to the various genome segment lengths, when coiled as described; their diameter is about 120 Å.¹⁶⁷ A super-helical organization of the RNP probably determines the dimensions. Partially complementary sequences in the 5′ and 3′ noncoding regions probably dictate the folded-back arrangement; sequences at either end of the coding region also contribute to specific packaging.¹⁶¹ Serial transverse sections through elongated buds of the WSN strain of influenza A show eight rods, seven around one, about 120 Å in diameter, extending for variable distances from the tip of the bud toward its proximal end; the distances correspond to the lengths of the various genome segments.¹⁶⁷ Tomographic reconstructions of purified filamentous influenza virus particles show that this internal organization is retained in the budded particle.²⁹ Interfering with packaging of one segment reduces packaging of others.¹⁶¹

Thus, there appears to be a sequential recognition mechanism to ensure a proper complement of genome segments, perhaps formally (although not structurally) analogous to the selection mechanism in dsRNA viruses. The RNA that forms the central element in the seven-around-one arrangement may have a particularly critical role; some evidence suggests that this segment is the one that encodes polymerase subunit PB2.¹⁶¹

The influenza N-protein, like those of the single-segment negative-strand RNA viruses, has two lobes with an RNA-binding groove between them, but the folded structures are not identical.²⁴⁸ The recombinant N forms trimers in a tight association determined by a loop, toward the C-terminus of the polypeptide chain, that inserts into a neighboring subunit as two antiparallel strands. The groove likely to accept RNA faces away from the threefold axis of the trimer. The relationship

FIGURE 3.20. Budding of enveloped viruses. **A:** Schematic of alphavirus maturation and budding. The core protein, C (blue), synthesized on cytosolic ribosomes, assembles with viral RNA into T = 4 nucleocapsids. The envelope proteins, E1 and pE2 (red), synthesized on endoplasmic reticulum (ER)-bound ribosomes, mature as they pass through the ER and Golgi, and pE2 is cleaved as it passes the trans-Golgi network to the cell surface. The nucleocapsid organizes the E1-E2 heterodimers into a T = 4 lattice as the particle buds. **B:** Electron micrograph of budding Semliki Forest virus. Arrow: complete virus particle just released. Arrowhead: nucleocapsid in the cytosol. Bar = 1,000 Å. **C:** Section through a tomogram of an isolated influenza virus particle. The hemagglutinin (HA) and neuraminidase (NA) spikes, which project from the membrane bilayer, have distinct outlines, and the blue curve at the bottom of the figure illustrates that the NA concentrates at one end of the particle. The M1-protein lines the inner membrane surface; the ribonucleoprotein complexes (RNPs) pack in longitudinal orientation inside the particle. Bar = 1,000 Å. **D:** Diagram of influenza virus budding. The HA (red), NA (blue), M2 proton channel (yellow), M1 protein (purple), and eight RNPs (gray and black) co-assemble at the site of budding. Host cell proteins (green) are excluded. NA and M2 enter the particle late in the process and cluster toward one end. (**B** adapted from Sjöberg M, Garoff H. Interactions between the transmembrane segments of the alphavirus E1 and E2 proteins play a role in virus budding and fusion. *J Virol* 2003;77:3441–3450. **C** adapted from Calder LJ, Wasilewski S, Berriman JA, et al. of the trimer configuration to N-protein interactions in the double-helical nucleocapsid has not yet been determined.

VIRAL MEMBRANES

Budding

Most enveloped viruses (except for the large and very complex poxviruses and probably some of the membrane-containing bacteriophages) acquire their membrane, a lipid bilayer

with associated proteins, by budding through some cellular membrane—the plasma membrane in many cases, the endoplasmic reticulum (ER), Golgi, or nuclear membrane in others (Fig. 3.20). These viruses direct insertion of their surface glycoproteins into the relevant membrane of the cell, through the usual cellular compartmentalization pathways. The driving force for budding then comes either from interactions between cytoplasmic tails of the glycoproteins and assembling or preassembled internal structures, from lateral interactions between glycoprotein subunits, or from a

combination of both. Retroviruses can bud without any glycoprotein at all: interactions between the myristoylated Gag protein and the lipid bilayer are sufficient to induce formation of a bud. Pinching off from the cell surface, or into the lumen of the ER or Golgi, appears in some cases (alphaviruses and flaviviruses) not to require a cellular pinching activity; assembly of viral components provides the force needed to distort the membrane bilayer. In many other cases, however, completion of budding requires that the virus recruit components of a cellular budding machinery.¹⁸¹ In the examples that have been studied in some detail (retroviruses, especially HIV), the virus redirects to the cell surface a set of protein complexes (the ESCRT machinery) that normally function at late endosomes, where they generate pinched-off invaginations into the endosomal lumen to create *multivesicular bodies*.^{85,216} The topology of viral budding from the cell surface is the same as the topology of luminal vesicle formation (away from the cytosol).

The lipids in the viral membrane derive from the cell, whereas the viral genome encodes the proteins. To a first approximation, the incorporated lipids represent a sample of those in the membrane through which the virus budded.¹²⁴ Viruses that emerge through the plasma membrane contain phospholipid and cholesterol in characteristic proportions, whereas those that emerge into the lumen of the ER contain almost no cholesterol. Cholesterol tends to increase the thickness of a bilayer by restricting free rotation about single bonds in the fatty acid chains of adjacent phospholipids.¹⁸³ The lengths of α -helical transmembrane segments in viral glycoproteins vary accordingly: from about 26 residues in flu (which buds at the cell surface) to 18 to 20 in yellow fever (which buds into the ER). Viral envelope proteins can also specify detailed specificities in lipid incorporation. For example, when present on a cell surface, the influenza virus envelope proteins (hemagglutinin [HA] and neuraminidase [NA]) associate with lipids characteristic of cholesterol-rich microdomains, and the lipid composition of the virus reflects this bias.^{199,221,254} The differential lipid composition of the viral membrane may contribute to membrane scission, which is ESCRT independent.⁴⁰ The viral M2 protein, a small, tetrameric ion channel that does not partition into microdomain lipids, incorporates at the base of the bud; an amphipathic helix in M2 appears to participate in pinching off the nascent virion.¹⁹⁴ The N protein also incorporates selectively at the base.²⁹

The two examples in Figure 3.20 illustrate features of the budding process. The structure of the nucleocapsid varies with virus type. It is a compact, spherical particle in the alphaviruses; a filamentous, helical nucleocapsid in paramyxoviruses and rhabdoviruses; and a multisegmented helical nucleocapsid in the orthomyxoviruses. The viral glycoproteins are anchored in the cellular membrane by a transmembrane hydrophobic segment (in some cases, a hydrophobic hairpin), and there is a small cytoplasmic domain. In alphaviruses (Fig. 3.20A), a core particle (nucleocapsid) assembles independently in the cytoplasm. Interactions between the core and the cytoplasmic tail of the glycoproteins then determine the location of budding. Lateral interactions of the glycoproteins probably assist the budding process. In orthomyxoviruses such as influenza (Fig. 3.20C), the M (*matrix*) protein associates with the nucleocapsid segments and with the inner face of the membrane, presumably by interaction with the cyto-

plasmic domains of the glycoproteins. M organizes both the glycoproteins and the nucleocapsids. Budding then proceeds by co-assembly of structures on both surfaces of the membrane. The two patterns of budding shown in Figure 3.20 are not fundamentally different; rather, they depend on the relative strength of core–core, envelope–envelope, and core–envelope contacts. In at least one case, a mutation has been shown to convert budding from one mode to the other.¹⁸⁸ Absolute specificity is sometimes violated in viral budding, leading to cases of phenotypic mixing, in which, for example, simian virus type 5 (SV5) glycoproteins can be found in the membrane of VSV. HIV buds with only a few copies of its glycoprotein on the virion surface, and some host–cell membrane proteins tend to incorporate nonspecifically into the particle.

The simplest enveloped virus particles—those of the alphaviruses and the flaviviruses—are icosahedrally symmetric.^{45,128,179,232,233} In these positive-strand RNA viruses, one-to-one interactions between the envelope glycoprotein and the nucleocapsid subunit appear to ensure coherence between external and internal structures (Figs. 3.20A and 3.21). The larger, negative-strand RNA bunyaviruses also have an icosahedrally symmetric envelope (a $T = 12$ lattice), but their internal structures are probably not icosahedrally organized, and the outer lattice is the major determinant of symmetry and stability.²³⁴ The rhabdoviruses have a helically organized shaft with a (probably hemi-icosahedral) cap at one end (Fig. 3.19). The orthomyxoviruses, like influenza A, bud out as variable, round or elongated structures with no overall symmetry, although there is probably considerable local order.¹⁶⁷ Retrovirus particles also appear to have no global symmetry.⁷⁹ The fluid character of a lipid bilayer means that the virus can form a closed structure without a perfect surface lattice. Defects in a protein layer that would produce unacceptable holes in a nonenveloped virus are tolerable if the barrier protecting the genome is a lipid membrane rather than a protein shell.

Internal Structures

The proteins on the internal side of viral envelopes are significantly more varied in design than those in the shells of nonenveloped viruses. The alphaviruses have subverted a serine protease to serve as the principal domain of the capsid subunit (C)⁴⁶ (Fig. 3.21). The protease is functional in the single step required to cleave C from the nascent polyprotein of these positive-strand RNA viruses. The core, sealed within the bilayer, can afford to be fenestrated. The hexamer and pentamer clusters of the protease domains do not contact each other, and interacting N-terminal arms maintain coherence of the $T = 4$ icosahedral lattice.²⁵⁸ These positively charged arms, like those of TBSV (Fig. 3.7), appear to knit the core together as well as to recognize and neutralize RNA. The hepatitis B capsid is also an open, almost lattice-like, structure, formed by a largely α -helical subunit that can assemble into either $T = 3$ or $T = 4$ shells.²⁰ The retroviral Gag precursor is usually anchored by an N-terminal myristoyl group to the membrane bilayer, and successive domains are separated by cleavage into radially organized layers^{84,247} (see Chapter 47). The structures of the various domains from HIV-1 Gag are known,⁷⁷ as are those of certain domains from a few other retroviruses.

FIGURE 3.21. Molecular organization of alphavirus particles. **Left:** Cross-section through an electron cryomicroscopy (cryoEM) three-dimensional image reconstruction of Sindbis virus.²⁵⁸ The labels point out the glycoprotein layer (E1 and E2) on the outside, anchored into the lipid bilayer through C-terminal transmembrane helices, with a short segment at the C-terminus of E2 in contact with the nucleocapsid protein (NCP). **Right:** The $T = 4$ glycoprotein surface lattice of the closely related Semliki Forest virus.¹³⁶ Superposed on a ribbon representation of the lattice of 240 E1 subunits is a more schematic diagram of the packing of E1 and E2. The E1 subunits are in red, yellow, and blue, representing respectively the three subdomains of the E1 ectodomain (see ribbon representation at **bottom, center**, in the same colors; the three subdomains are labeled I, II, and III). The approximate location of the E2 ectodomain is in green. The numerals 5, 3, and 2 designate positions of fivefold, threefold, and twofold icosahedral symmetry axes; black triangles designate local threefold positions in the $T = 4$ surface lattice. The E2 subunits clamp the E1 subunits in place; exposure to low pH releases the clamp. At the bottom left is a ribbon representation (blue) of the nucleocapsid protein (an autoprotease with a trypsin-chymotrypsin-like fold; the cleavage generates its C-terminus, which remains bound in the catalytic cleft as an inhibitor); N and C designate its termini.⁴⁶

Surface Envelope Proteins

Most viral envelope proteins are so-called type I membrane proteins, with a single transmembrane α -helix linking an N-terminal ectodomain and a C-terminal tail inside the membrane. Some (e.g., the influenza virus neuraminidase) have the opposite polarity (type II). In flavivirus structural proteins, which derive from a polyprotein precursor (as in most positive-strand RNA viruses), the anchor is an α -helical hairpin that traverses the membrane twice.³⁶ The transmembrane helices have been resolved in cryoEM studies of alphaviruses and flaviviruses^{159,255,258} (Fig. 3.21). Contacts between the cytoplasmic tails of viral envelope glycoproteins and target sites on the underlying core of matrix subunits generally determine specificity of envelope protein incorporation (Figs. 3.20D and 3.21). These interactions often involve a short segment of envelope polypeptide, fitting against a site on the internal protein.^{19,135,171} Individual interactions are weak, and bilayer disruption by nonionic detergents readily dissociates them.

The proteins on the outer surface of an enveloped virus must carry out at least two functions: receptor binding and fusion. In addition, there may be a receptor-destroying enzyme (e.g., the influenza virus neuraminidase or the coronavirus esterase) to promote viral release. The membrane of influenza A contains a fourth activity: a proton channel that assists uncoating and transcriptase activation (M2). In certain cases (e.g., rhabdoviruses and retroviruses), the receptor-binding and

fusion activities are combined in a single protein; in others (e.g., paramyxoviruses), there are two distinct proteins to carry out these functions. Structures of viral fusion proteins are described later in the subsection on membrane fusion.

STRUCTURAL BIOLOGY OF VIRUS ENTRY

Receptor Binding

There are no simple generalizations about virus receptors and how they bind with viral surfaces (Fig. 3.22). We note two points here. The first is that most viruses have evolved a mechanism to avoid “getting stuck” at the cell surface when emerging from an infected cell. Many viruses simply bind weakly to their receptors, and thus can dissociate in a reasonable time. The virulence of polyomavirus in mice is inversely related to viral affinity for its sialoglycoconjugate receptor (Fig. 3.22A), demonstrating that spread in the animal host, rather than entry into cells, is the principal correlate of pathogenesis.¹² Like polyoma, influenza virus recognizes a sialic acid-containing carbohydrate for cell attachment¹⁷⁶ (Fig. 3.22B). A receptor-destroying enzyme (neuraminidase) is present on the surface of the virion; its activity allows release of newly assembled virions from the cell surface through which they have budded.¹⁷² The neuraminidase is thus required for effective spread of the virus, and the enzyme is the target of anti-influenza drugs, developed

FIGURE 3.22. Examples of virus–receptor interactions. **A:** Simian virus type 40 (SV40) and polyomavirus. **Left:** Pentamer of SV40 VP1, showing location of the interaction on the outward-facing surface of the subunit. **Right:** Detailed views of the receptor-binding sites for the two viruses (boxed region in the **left-hand panel**), showing interactions of distinct glycan structures (from glycolipid headgroups) with homologous sites on the VP1 subunits. **B:** Influenza virus: sialic acid–binding site on the HA1 “head.” **C:** Severe acute respiratory syndrome (SARS) coronavirus: docking of the ACE2 receptor with the receptor-binding domain (RBD) of the viral glycoprotein spike.¹³⁷ **D:** Adenovirus penton-fiber knob (**top view**), bound with domain 1 of the multi-Ig domain receptor, CAR (coxsaekievirus-adenovirus receptor), which helps recruit type 2 adenovirus to cell surfaces.²⁰¹ **A** adapted from Neu U, Woellner K, Gauglitz G, et al. Structural basis of GM1 ganglioside recognition by simian virus 40. *Proc Natl Acad Sci U S A* 2008;105:5219–5224. **B** adapted from Whittle JR, Zhang R, Khurana S, et al. in part by exploiting knowledge of the NA structure.²³⁵ HIV-1 has several mechanisms for down-regulating its receptor (CD4) after infection, both to avoid envelope–receptor interactions within the secretory pathway and to facilitate viral release after budding (see Chapter 49).

The second general point is that some viruses require a cascade of at least two distinct receptors—one for initial cell attachment and a second for triggering fusion or penetration. The receptor used for initial attachment may be a widely distributed molecule, such as sialic acid or other glycans (heparan sulfate for herpes simplex virus-1), or it may be a quite specific protein, such as the adenovirus receptor, CAR, or the HIV-1 receptor, CD4 (Fig. 3.22C). The molecule that triggers fusion or penetration is sometimes called a *co-receptor*—for example, the chemokine receptors for HIV-1. In the case of HIV-1, CD4 primes the envelope glycoprotein to bind the co-receptor, which in turn induces fusion activation. An obligate order of this sort may turn out to be relatively common.

Viruses that mutate to avoid recognition by the immune system (e.g., influenza, HIV) have sometimes evolved structural features to sequester their conserved, receptor-binding surface from interaction with antibodies. The footprint of an antibody-combining site is substantial, and thus even if a receptor site is exposed, it rarely matches the full extent of the surface within which amino acid residue changes will lower antibody affinity and hence escape neutralization.⁵⁰ While some viral receptor sites (e.g., those on certain picornaviruses: Fig. 3.4) lie within a groove or pocket too narrow to admit the antigen-combining end of an antibody (sometimes called a “canyon”^{195,196}), others are fully exposed or even protruding (Fig. 3.22D).¹³⁷ Moreover, antibodies with unusually long or prominent heavy-chain CDR3 loops can penetrate relatively tight cavities.

An Irreversible Step Between Assembly and Entry

Assembly of TMV protein and RNA into infectious particles was among the key observations that triggered thinking about viral symmetry.⁵⁶ *In vitro* self-assembly of components from the mature virion into complete infectious particles is, however, an exceptional characteristic of the simplest plant and bacterial RNA viruses. A far more general property of virus assembly pathways is a modification, often a simple proteolytic cleavage, that “primes” the particle for large-scale, irreversible events accompanying entry. Loss of a scaffolding protein is a particularly extreme example of such a modification. Poliovirus and other picornaviruses assemble from VP0, VP1, and VP3, but autolytic cleavage of VP0 into VP4 (an internal peptide) and VP2 accompanies assembly (see Chapter 16). When receptor binding triggers expansion of the viral shell, exit of VP4 renders the rearrangement irreversible.^{15,100} The receptor is a catalyst that lowers the energy barrier to an irreversible reorganization.²²⁶ The function of this reorganization is viral entry, and the triggering mechanism has evolved to occur only in an appropriate location. Reoviruses have an outer protein, $\sigma 3$, that caps the penetration protein, $\mu 1$.^{64,140} Proteolytic removal of $\sigma 3$ is required to render the particle competent to attach and penetrate (see Chapter 44). There is, in addition, an essential autolytic cleavage of $\mu 1$.¹⁶⁵ The HA of influenza virus folds in the ER into a stable, trimeric structure. Cleavage of one peptide bond in HA by the protease furin in a compartment late in the secretory pathway primes the

FIGURE 3.23. Fusion of two lipid bilayers. **A:** Two parallel bilayer membranes. There is a substantial barrier to close approach. **B:** Hemifusion stalk. **C:** Proposed transition structure. **D:** Fusion pore (before lateral expansion). **E:** Hemifusion diaphragm. **F:** Some models include perforation of the hemifusion diaphragm as a productive step toward fusion-pore formation, but diaphragm formation is more often considered a dead end. (Adapted from Jahn R, Lang T, Sudhof TC. Membrane fusion. *Cell* 2003; 112:519–533.)

protein to undergo a dramatic, low-pH-triggered rearrangement, which mediates fusion of viral and target cell membranes. In effect, cleavage renders the virion form of HA metastable, but the barrier to rearrangement is so great at neutral pH that no conformational change occurs. Proton binding in the low pH environment of the endosome removes this barrier and triggers a refolding of the HA protein. Protons have the role taken in other cases by a co-receptor (e.g., the chemokine receptors for HIV-1). The expression “spring loaded” has been used to describe the state of HA at neutral pH after cleavage to HA₁ and HA₂.³² *Jack-in-the-box* might be a comparable image for poliovirus after cleavage of VP0.

Membrane Fusion Bilayer Fusion

The bilayer fusion reaction common to all the enveloped viral entry pathways is shown schematically in Figure 3.23. It is believed to pass through an intermediate known as a *hemifusion stalk* (Fig. 3.23, top center), in which the two apposed leaflets have fused, but not the distal ones.^{130,147,184,205} Hemifused bilayers can then form either a *fusion pore* (Fig. 3.24, right) or a structure in which the two distal leaflets create a single bilayer. This state, which can spread laterally, is called a *hemifusion diaphragm* (Fig. 3.23, bottom center). Bilayers do not fuse spontaneously (e.g., concentrated liposomes are quite stable), because the reaction in Figure 3.23 has a high activation barrier, both at the step between the precursor bilayers and the hemifusion stalk and at the step between the hemifusion stalk and the fusion pore. A newly opened pore may revert to a hemifusion structure (*flickering*), and the largest kinetic barrier may be for the step in which the pore dilates rather than reverts.^{148,184}

Conformational Rearrangements in Viral Fusion Proteins

Viral fusion proteins must lower the kinetic barriers to fusion of viral and cellular membranes. They do so by undergoing dramatic conformational rearrangements that lead to tight apposition of the two membranes.¹⁰⁶ We can thus distinguish *prefusion* and *postfusion* conformations, as well as potential intermediates. The viral fusion proteins analyzed in detail at the time this

FIGURE 3.24. Influenza virus hemagglutinin (HA): structure and fusion-promoting conformational change. **A:** The HA polypeptide chain. HA₁ in blue; HA₂ in yellow (fusion peptide), red (remainder of ectodomain), and gray (transmembrane and internal segments). The position of the fusion activation cleavage between HA₁ and HA₂ is a narrow white stripe, indicating excision of a single residue in many cases. The location of disulfide bonds is shown schematically above the bar. Residue numbers correspond to positions in the HA of strain X-31. **B:** The HA ectodomain monomer, in prefusion and postfusion (the latter, HA₂ only) conformations to the left and right, respectively. HA₁ in blue; HA₂ in red. The postfusion HA₂ structure illustrated here lacks the fusion peptide as well as additional residues at both ends of the chain. **C:** The HA ectodomain trimer, in prefusion and postfusion (the latter, HA₂ only) conformations, to the left and right, respectively. HA₁ in black and white; HA₂ in colors showing various segments of the ectodomain, so that their reconfiguration during the transition from the pre- to the postfusion structure is evident. Note the loop-to-helix transition in the C-terminal portion of the red segment. **D:** Model for the coupling of the fusion-promoting conformational change in HA to the fusing membranes. **Stage 1:** Prefusion conformation. Red asterisk shows position of fusion peptide at N-terminus of HA₂. Engagement with a sialic acid receptor in the target membrane is not shown. **Stages 2 and 3:** Transition to an extended intermediate, in which the three fusion peptides of the trimer associate tightly with the target cell membrane. The fusion peptide is shown schematically as an amphipathic helix in the membrane surface—the actual structure is probably an amphipathic helical hairpin.^{143,144} Proton binding at low pH dissociates HA₁ from HA₂, although the two fragments remain tethered by a disulfide bond. **Stage 4:** During the transition of HA₂ from intermediate to postfusion conformation, the fusion peptide and transmembrane segment come together, thereby bringing the two membranes close enough to fuse. The final, postfusion conformation of HA₂ is locked in place by the “cap,” shown in the **inset**, in which residues near the C-terminus of the HA₂ ectodomain interact with residues between the fusion peptide and the long, central α -helix.⁴¹

chapter went to press fall into three structural classes, generally designated I, II, and III. Common characteristics of fusion by all three classes are insertion of a segment of the fusion protein into the target membrane and refolding of the protein so that this inserted segment and the transmembrane anchor are adjacent, thereby bringing together cell and viral membranes. The three structural classes probably represent meaningful evolutionary categories, as a cellular representative of at least one of the classes very closely resembles its viral orthologs.

Influenza Virus Hemagglutinin, a Class I Viral Fusion Protein

The defining characteristics of class I fusion proteins are synthesis as a precursor that requires a proteolytic cleavage for activation (often, but not always, by a furin-like enzyme in the trans-Golgi network); trimeric oligomerization in both pre- and postfusion conformations, based on a central, three-chain α -helical coiled-coil in the postfusion conformation; and presence of a hydrophobic *fusion peptide* near the N-terminus created by the activating cleavage. The fragment C-terminal to the cleavage, with the viral transmembrane segment, is the fusogen; the fragment N-terminal to the cleavage, in many but not all cases, is a receptor-binding structure, which generally dissociates when suitably triggered, releasing its grip on the fusogenic fragment. The final, postfusion structure is a *trimer of hairpins*, as described later.

Influenza virus HA is the best-studied class I fusion protein.²⁴⁴ HA₀, the uncleaved precursor, and HA₁/HA₂, the cleavage product, are almost identical in structure, except for a local shift that tucks the fusion peptide (the N-terminus of HA₂) between the played helices of the central coiled-coil (Fig. 3.24B). Unless induced to refold by lowered pH or by heat, HA₁/HA₂ is very stable. HA₁ forms a globular domain at the “top” of the molecule, with a binding pocket (Fig. 3.24B,C) for the receptor, sialic acid.²³⁷ Proton-induced rearrangement of HA (Fig. 3.24B–D) has two essential features. The first is ejection of the protected hydrophobic fusion peptide (Fig. 3.24D, transition from stage 2 to stage 3). The second is folding back of the fusion protein (HA₂) so that the N-terminus (the fusion peptide) and the C-terminus (the viral membrane anchor) come together (Fig. 3.24D, transition from stage 3 to stage 4).^{26,41,210} A likely intermediate state, for which there is experimental evidence in the case of HIV-1 gp41,^{62,81,108} is an extended structure with the fusion peptide buried in one membrane and the anchor in the other (Fig. 3.24D, stage 3). Zipping up of the C-terminal part of the HA₂ ectodomain along the core of this *prefusion intermediate* will cause the transmembrane anchor and the fusion peptide to approach each other. Formation of an intricate “cap” on the three-helix core snaps the refolded structure in place (Fig. 3.24D, inset).⁴¹ Note that the zipping-up process cannot be symmetrical, because the trimer would otherwise encase itself in lipid. The C-terminal outer-layer segments are long enough, in their unfolded state, to reach around the core of the refolding trimer. Contacts between the three outer-layer chains in the refolded structure are minimal, so that the three can zip up independently and at different rates. Several rearranged fusion proteins might be required to surround and induce a hemifusion stalk. Estimates from measurements of fusion by HA expressed on a cell surface and of fusion of virions with a supported bilayer *in vitro* indicate that on average, three HA trimers participate in fusion pore formation.^{59,76}

Other Class I Fusion Proteins

The postfusion conformation of HA is a trimer of hairpins. The N- and C-termini of each subunit lie at the same end of the elongated protein, and the polypeptide chain traverses the length of the molecule just twice—once from the N-terminus to the distal end, and once back to the C-terminus—with some modest complexity in the distal loop. The *inner core* is a trimeric coiled-coil; the *outer layer* of each subunit is largely extended chain, with a short helical segment. Other class I fusion proteins have the same postfusion characteristics (Fig. 3.25), the structure in the case of HIV-1 being particularly simple, as both inner core and outer layer are helical.^{18,37,145,239} The two helices are sometimes designated HR1 or HRA and HR2 or HRB (*helical region 1* or *A* and *helical region 2* or *B*, respectively), but the postfusion HA structure illustrates that identification of two helical regions may not always be informative. Moreover, a major part of the central coiled-coil in postfusion HA₂ is not even helical in the prefusion trimer—another reason why “HR1” and “HR2” are partly misleading designations. Note further that in influenza HA, the N-terminal parts of HA₂ are on the outside of the spike in the prefusion conformation and on the inside in the postfusion conformation (Fig. 3.24). The protein turns itself inside out during the refolding.

FIGURE 3.25. Postfusion conformations of three class I fusion-protein ectodomains.^{37,220,238,239,260} Only the folded-back cores of the proteins are shown. The fusion peptide extends from the N-terminus of the trimeric bundle; the transmembrane segment is at its C-terminus. Compare with the postfusion conformations of influenza virus HA₂ in Figure 3.24C and of the paramyxovirus human parainfluenzavirus 3 (hPIV3) F2 protein in Figure 3.26B. The HIV gp41 structure is particularly simple: a six-helix bundle with a relatively short loop (dotted lines) between the inner (N-terminal) and outer (C-terminal) helices (HR1 or HRA and HR2 or HRB, respectively). A 200-residue domain intervenes between the postfusion inner and outer layers of severe acute respiratory syndrome virus-coronavirus (SARS-CoV) S2.

The postfusion conformation of a class I fusion protein is the most stable one it can adopt when constraints such as the covalent linkage between the two fragments have been removed, and proteins in this conformation have therefore been easier to prepare and study than have prefusion conformers or protein models for intermediate structures. It is important to emphasize, however, that no inferences can be drawn about the prefusion structures of these proteins from their trimer-of-hairpins postfusion conformers.

One other class I fusion protein for which both pre- and postfusion structures have been determined is paramyxovirus F^{43,52,132,249,250} (Fig. 3.26). It has a cleavage site just N-terminal to a fusion peptide, which resembles (in being hydrophobic and relatively glycine-rich) the fusion peptides in gp160 and HA₀. Cleavage is essential for fusion activity, but not for the fusion-promoting conformational change. In the mushroom-like, prefusion conformation, a three-strand α -helical coiled-coil, the stem of the mushroom, is the C-terminal part of the ectodomain. It connects directly (in the intact protein) to the transmembrane segment. The strap between the coiled-coil stem and the head of the mushroom is an ordered, but very extended, stretch of polypeptide chain, which wraps around the outside of the globular cap. The cap also presents a groove

to accommodate the fusion peptide. A separate protein (designated HN, H, or G in various paramyxoviruses) binds receptor and triggers the conformational rearrangement of F (see Chapter 33). In the refolded state, no parts of the protein dissociate (as they do from HA and gp120/gp41), but a long, three-strand coiled-coil forms from segments (all C-terminal to the cleavage site) that are part of the globular “cap” in the prefusion structure.²⁴⁹ The C-terminal coiled-coil comes apart so that the C-terminal helices can fold back up along the outside of the newly formed coiled-coil. The length of the strap between the globular domains and these helices, which probably dissociate, unfold, translocate, and refold as they zip along the coiled-coil core, allows sufficient flexibility for this transition. None of the trimer contacts in the prefusion state are fully conserved in the postfusion structure, raising the possibility of a monomeric intermediate, but the overall geometry does permit the assembly to refold as a trimer without such dissociation.

The Flavivirus Envelope Subunit (E), a Class II Fusion Protein

Class II fusion proteins have been found only on alphaviruses, flaviviruses, and bunyaviruses, all of which have compact, icosahedrally symmetric virions. The defining characteristics of fusion

FIGURE 3.26. The paramyxovirus fusion protein (F). **A:** The ectodomain trimer of simian virus type 5 (SV5) F in its prefusion conformation. F1 is in black and white; F2, in color. The order of colors corresponds to the order of colors in influenza HA₂ in Figure 3.24C. The viral membrane would be at the bottom of the figure: the polypeptide chain of F2 enters the membrane immediately following the yellow segment, which forms a three-chain coiled-coil in the prefusion conformation. **B:** The postfusion conformation of F from another paramyxovirus, human parainfluenzavirus 3 (hPIV3). Color scheme as in **A**. Note that the red and blue segments toward the N-terminus of F2 have refolded into a three-chain coiled-coil, projecting the fusion peptide (not shown) toward the “top” of the trimer. Compare these segments with those of corresponding color in Figure 3.24 C. Also note that the yellow segments at the C-terminus of the F2 ectodomain no longer form a coiled-coil, but rather align along the outside of the coiled-coil generated by the (red and blue) N-terminal region. **C, D:** Pre- and postfusion conformations of monomers, with F1 in blue, F2 in red, and fusion peptide (N-terminus of F2) in yellow. Numbers in **C** correspond to SV5 F; numbers with “h” in **C** and **D**, to hPIV3 F. (Courtesy of Ted Jardetky, Stanford University.)

FIGURE 3.27. Membrane fusion induced by the flavivirus envelope protein, E. **Diagram lower left:** Dimer-clustered packing of E on the virion surface. The three domains of each protein ectodomain are in red, yellow, and blue. **Numbered sequence:** likely series of conformational states of E and their links to viral and cellular membranes. Structures for states 1 and 5 are known; those for states 2 to 4 are inferred from indirect data. One subunit in each dimer or trimer is colored as in the schematic; its partner(s) are in gray. **1:** E dimer on the virion surface. The ectodomain terminates in a helical hairpin called the *stem* (light blue) on the surface of the viral membrane (lower gray bar) and connects with a transmembrane helical hairpin. Blue arrow from above symbolizes a receptor interaction with domain III (blue). **2:** Exposure to low pH (in endosomes) dissociates the E dimer, allowing the subunits to project outward, so that the fusion loops (tip of the yellow domain II) encounter the endosomal membrane (upper gray bar). **3:** Initial trimer association, requiring some rearrangement across the surface of the virion. Arrows show presumed pattern of folding back; upper arrows: domain III (blue) flips over against domain I (red); lower arrows: the stem refolds to “zip up” alongside the trimer clustered domain II (yellow). **4:** Stem continues to reorganize (asymmetrically), pulling the two membranes together. The fusion loops must be firmly anchored in the target membrane. **5:** Formation of a fusion pore allows the refolding to finish, so that all three stems and all three fusion loops cluster together, restoring full threefold symmetry.

proteins in this class are a three-domain subunit, with an internal, hydrophobic *fusion loop* at the tip of the elongated second domain; association with a viral “chaperone” protein, which must be cleaved to prime the fusion process; and formation of a stable trimer in the postfusion state, with the three fusion loops and the three C-terminal, transmembrane anchors clustered at one end (Fig. 3.27). The fusion proteins are known, respectively, as E1 and E in alphaviruses and flaviviruses; the chaperones, as pE2 and prM. Cleavage of the latter proteins generates E2 and M, with release (at some point in the fusion process) of a “pre” fragment, which covers the fusion loop of E1 or E in the unprimed state.

The flavivirus E protein tiles the surface of the virion as a tightly associated dimer¹²⁸ (Fig. 3.11). There are 90 such dimers; their packing is not a quasiequivalent, T = 3 arrangement, but a herringbone-like pattern. On an immature particle,

before cleavage of prM (the chaperone), E forms heterodimers with prM rather than homodimers with itself.¹²⁸ Substantial structural rearrangements accompany maturation and dissociation of the “pre” fragment.^{138,252,253} Likely steps in the fusion process, deduced from comparison of the pre- and postfusion conformations,^{22,154,155,187} are illustrated in Figure 3.27. The underlying similarity of class I- and class II-mediated fusion should be evident. The fusion loops insert only partway into the outer leaflet of the target membrane.

VSV-G, a Class III Fusion Protein

Class III fusion proteins mediate penetration of particles as distinct as the rhabdoviruses^{191,193} and herpesviruses,^{7,109} as well as the insect baculoviruses.^{6,120} There appears to be no proteolytic cleavage, either of the fusion protein itself or of a chaperone, required for priming, and the fusion-inducing conformational

FIGURE 3.28. Membrane fusion induced by the vesicular stomatitis virus (VSV) glycoprotein (G). Sequence of conformational events as in Figures 3.24 and 3.27. **1:** Prefusion trimer of VSV G on the virion surface. Subunits colored in red, blue, and green. Red asterisk: fusion loops of the green and blue subunits. **2:** Conformation of one subunit of the trimer in **1**, now colored to show a central, red domain and a set of peripheral, blue domains. An axial helix (lighter blue) joins part of the central domain to the set of peripheral domains. In the low-pH-triggered rearrangement, the blue regions reorient with respect to the red domain (arrow). **3:** Presumed initial rearrangement, in which the domain bearing the fusion loops projects toward the cellular (endosomal) membrane, into which the fusion loops insert. The axial helix remains, augmented by a segment derived from its connection to the peripheral domains. Arrows indicate likely reorganization that follows: the central domain flips over and the *stem* at the C-terminus of the ectodomain zips up, bringing together the two membranes. **4:** Formation of a fusion pore (not shown explicitly—compare the last two stages in Figure 3.27) allows the three sets of fusion loops and the membrane-proximal segments of the ectodomain to cluster. Part of the stem rearrangement includes formation of a helical segment, which forms a six-helix bundle with the central-region helix. The conformational details thus have features of both class I fusion proteins (formation of a six-helix bundle) and of class II fusion proteins (preconfigured, internal fusion loops that insert into the target membrane).

change is in at least some cases reversible.¹⁹² That is, virions inactivated by prolonged incubation at pH less than 6 can be reactivated by raising the pH to neutral or above, and both conformations of the multidomain, trimeric protein can be obtained from the same protein preparation.

VSV-G, the only protein on the surface of the virion, has two hydrophobic loops that can interact with membrane lipids⁶⁷ (Fig. 3.28). The connectivity of the strands joined by these fusion loops is different from the connectivity in domain II of the class II proteins (i.e., the domains themselves have different folds), but the general picture is quite similar: hydrophobic residues (including at least one tryptophan) are displayed on tightly structured loops at the tip of an elongated domain. In the prefusion conformation of VSV-G, these domains face the viral membrane around the periphery of the trimer.¹⁹³ In the postfusion conformation, they cluster around the three-fold axis¹⁹¹ (Fig. 3.28; compare the “inside-out” transition in influenza HA, Fig. 3.25).

In the rhabdovirus G protein, a core domain contains residues from the N-terminal segment of the polypeptide chain and residues from near the C-terminal part of the chain: it is a framework around which the rest of the molecule reorients. Two other domains form a jointed, two-part fusion machinery. The result of their rotations relative to the core domain (and to each other) is to move the fusion loops away from the viral membrane and toward the target membrane. In a likely extended intermediate conformation (shown in Fig. 3.29, but

for which there are no direct structural data), the C-terminal segment still connects toward the viral membrane in one direction, while the fusion loops interact with the target membrane in the opposite direction. In the fully rearranged, low-pH conformation, the C-terminal segment has zipped up along the fusion domains, much like in the flavivirus fusion transition.

The herpesvirus fusion protein, gB, looks like an elongated version of VSV-G.¹⁰⁹ This unexpected similarity between fusion proteins of a DNA virus and a negative-strand RNA virus has allowed information about one protein (e.g., the identification of the rhabdovirus fusion loops) to be carried over to the other.¹⁰² Only the postfusion structure of gB has been determined so far. The gB conformational transition is triggered not by changes in pH, but rather by receptor binding to another surface protein, gD.^{31,127} A binding-induced conformational change in gD leads to the reorganization of gB, with participation of yet another protein, the gH/gL heterodimer.^{48,150}

Penetration by Nonenveloped Viruses

Nonenveloped viruses must breach a membrane to access the cytoplasm or nucleus of a cell, but unlike their enveloped cousins, they cannot do so by membrane fusion. One can imagine two classes of models by which a nonenveloped particle, bound at the surface of a cell or taken up into an endosome or other internal compartment, translocates itself (or its genome) across the intervening lipid bilayer (i.e., *penetrates*). Models of one

class (*pore formation*) invoke creation of a pore, through which the viral genome is drawn into the cell. Those of the other class (*membrane perforation*) postulate a more extensive, transient disruption of a cellular membrane (e.g., the membrane of an endosome), in order to admit the virion (in altered form) into the cytosol. Either of these models is consistent with a variety of distinct molecular mechanisms. In all well-studied cases, binding of a receptor, co-receptor, or some other ligand induces a conformational change in the virus particle, with consequent exposure of previously buried, hydrophobic structures. Examples of the exposed components are a pore-forming peptide or protein, frequently N-terminally myristoylated; a protein with membrane-interacting, hydrophobic loops; and a lipase. Certain bacterial viruses, such as the T-even bacteriophages, have much more elaborate injection structures that couple the induced conformational change to mechanical force generation.

Released or exposed virion components that bear an N-terminal myristoyl group include VP4 of picornaviruses,⁴⁷ VP2 of polyomaviruses,¹⁹⁸ and μ 1N of reoviruses.¹⁶⁶ Myristoyl groups target proteins to membranes, and it is logical to suppose that exposure of the myristoylated peptide protein leads it to associate with membranes and ultimately to contribute to penetration. In at least one case (reovirus μ 1N), pore-forming activity has been shown directly.

Receptor binding by picornaviruses triggers a rearrangement or destabilization of the virion, exposing the myristoylated VP4 as well as a hydrophobic N-terminal segment of VP1.^{24,78,89,100,101} Evidence from electron microscopy suggests that a poliovirus particle, bound to membrane-anchored receptors and therefore altered in this way, interacts closely with the receptor-bearing membrane.^{25,228} In one proposed model, the exposed hydrophobic segments form a pore in the endosomal membrane, through which the genomic RNA passes.^{24,110} This model requires a mechanism for destabilizing secondary-structural elements in the RNA in order to make translocation possible. One candidate helicase would be a ribosome or ribosome-associated factor, by analogy with an uncoating mechanism established (*in vitro*) for certain positive-strand RNA plant viruses. With those viruses, exposure of the 5' end of the RNA (e.g., through expansion of the virion induced by intracellular ionic conditions) leads to association of ribosomes with the still largely packaged RNA genome, and progress of the ribosome along the message-sense genome appears to uncoat the particle.^{203,204,245} A similar mechanism could, in principle, draw RNA through a membrane pore as well as through an opening in the viral shell. An alternative model for picornavirus penetration would involve membrane disruption (a "large" pore). If receptor binding and subsequent endocytosis caused the shell to dissociate, rather than just to expand or reorganize, components of the dissociated shell could be the agents of membrane disruption, and concomitant RNA unwinding would not be required.

For adenoviruses, the entry route is endosomal uptake; penetration proceeds by disruption of the endosome containing the virion.^{75,92} The subviral particle admitted to the cytoplasm lacks pentons as a result of events triggered by receptor and co-receptor binding. Exposure of an internal viral protein, pVI, which depends on the activity of a packaged viral protease, leads to perforation of the endosomal membrane.^{206,241} The membrane-disrupting properties of pVI

may come from an N-terminal amphipathic α -helix.¹⁵⁸ Following penetration, the partially stripped virion migrates to a nuclear pore, where it disassembles and liberates its DNA for nuclear import.

Like adenoviruses, the dsRNA viruses release into the cytoplasm an intact, roughly 700-Å-diameter subviral particle (called the *core* in the case of reoviruses and the *double-layered particle* in the case of rotaviruses). This inner capsid particle never uncoats, however, as it contains all the enzymes necessary for messenger RNA (mRNA) synthesis and modification (see Chapters 44–46). The penetration protein of reoviruses is the outer-shell trimer, μ 1.^{38,111,165} On the virion, this protein is associated with a "chaperone" subunit, σ 3; degradation of σ 3 (by proteases in the gut or by cathepsins in endosomes) and autocleavage of μ 1 allows μ 1 to release a myristoylated, N-terminal peptide (μ 1N). The released peptide, up to 600 copies of which could emerge from a single virion, forms membrane pores. The penetration protein of rotaviruses is VP4, which must also be cleaved (by intestinal trypsin) to activate entry. VP4 is not a homolog of μ 1, although rotaviruses do have such a homolog, VP6, which appears to have a purely structural role.¹⁴⁹ The conformation of VP4 changes quite dramatically when cleaved to VP8* and VP5* by trypsin: the initially disordered "spikes" of this protein become rigid projections,^{55,202} which rearrange further in subsequent, penetration-inducing steps.^{63,251} VP5* presents a set of hydrophobic loops, noticeably similar to the fusion loops of class II and class III fusion proteins, that direct membrane association.¹²³ The observed conformational transitions of VP5* resemble the folding back of fusion proteins, but there is yet no evidence for a direct coupling of these rearrangements to membrane breakage.

Parvoviruses have a single kind of coat subunit (see Fig. 3.5), but a few of the 60 copies of this protein have an extra, N-terminal domain, which is sequestered within the virion. This domain is a phospholipase A₂. During entry, it moves to the outside of the particle, to which it nonetheless remains tethered. Its lipase activity is essential for entry.⁷³

Disruption of the membrane of an endosome or other intracellular compartment is a relatively nonspecific process, in the sense that other particles within the same compartment can accompany the active particle into the cytosol, once the membrane is breached. Thus, several of the viruses described earlier mediate penetration of bacterial toxins that lack their own cell-entry mechanism, and other viruses (e.g., adenoviruses or nondefective parvoviruses) can complement a phospholipase-deficient parvovirus.

Perspectives

Viral particles have a single mission: to transport the viral genome from an infected host cell to a noninfected host cell and to deliver it into the cytoplasm or the nucleus in a replication-competent form. The target can be a neighboring cell, a cell elsewhere in the host organism, or a cell in another organism. The process starts in an infected cell with the packaging of the viral genome and accessory proteins into a new virus particle, which is released into the extracellular space. When the virus contacts the surface of a new host cell, a complex series of events ensues tightly coordinated in time and space. These events include binding to receptors and signaling, often followed by endocytic internalization, vesicular trafficking, membrane penetration, cytosolic transport, and nuclear import (Fig. 4.1). Uncoating is an integral part of the process; the virus particle is modified, destabilized, disassembled, and eventually the genome, present in a protected and condensed form in the virion, is decondensed and exposed in a replication- or transcription-competent form. The progression of a virus particle through its entry program depends critically on cellular functions. The *Trojan horse strategy* that is used is necessary because the particles are simple and capable of limited independent functions.

This chapter describes some of the general concepts that govern cellular entry of animal viruses. For information about the entry of specific viruses and virus families, the reader is referred to the virus chapters. Information relevant to the

topics covered here also can be found in numerous reviews that cover early virus cell interactions.^{43,81,100,109,110,124,150,167,212}

THE BARRIERS

The first barrier that incoming viruses must overcome is the glycocalyx, a layer of glycoconjugates that covers the external surface of cells. It is composed of glycoproteins, glycolipids, and proteoglycans. The composition and thickness of this layer is variable. By binding to oligosaccharides, many viruses make use of the glycocalyx for initial attachment.

The next barrier is the plasma membrane. Responsible for the cell's exchanges with the environment, it is the most complex and most dynamic of all cell membranes. The composition and properties are regulated by the endocytic and secretory pathways and by a continuous association and disassociation of proteins that interact with the cytosolic leaflet. The plasma membrane is a highly sensitive organ for recognizing and responding to external stimuli. Viruses take advantage of this during entry.

After clearing the plasma membrane by direct penetration or by exploiting endocytic pathways, viruses and viral capsids have to reach sites deeper in the cytoplasm. The cortical actin network underneath the plasma membrane and extreme crowding constitute major barriers to movement within the cytoplasm.¹⁸⁴ Finally, because many viruses replicate in the nucleus, the genome and accessory proteins must travel to the nucleus and cross the nuclear envelope. This requires cooperation between the incoming virus and the nuclear import machinery.²¹¹

VIRUS BINDING TO THE CELL SURFACE

Viruses can only infect cells to which they can bind. Binding occurs to *attachment factors* and *virus receptors* on the surface of the cell. To a large extent, the identity, distribution, and behavior of these cellular components determine which cell types, tissues, and organisms a virus can infect. The receptors also define, in part, the pathogenic potential of a virus as well the nature of the disease that it causes.

Virus receptors can be defined as cell surface molecules that bind the incoming viruses to the cell, and, in addition, promote entry by (a) inducing conformational changes in the virus that lead to priming, association with other receptors, membrane fusion, and penetration; (b) transmitting signals through the plasma membrane that lead to virus uptake or penetration and prepare the cell for the invasion; or (c) guiding bound virus particles into a variety of endocytic pathways.¹²⁴ *Attachment factors* help to concentrate the particles on the cell's

FIGURE 4.1. Stepwise entry of animal viruses. The entry of animal viruses involves a series of steps that start with virus binding to the cell surface. Binding is multivalent and involves cell surface molecules serving as passive attachment factors or receptors that are more active in that they activate signaling pathways, induce conformational changes in the virus, or mediate endocytic internalization. Although some enveloped viruses are able to fuse with the plasma membrane, the majority of viruses rely on internalization by different endocytic mechanisms. Internalization is followed by transport to secondary organelles (usually endosomes), where the virus receives cues to trigger the penetration process. After reaching the cytosol, the viruses or viral capsids are transported to the site of genome uncoating and replication. For most DNA viruses and a few RNA viruses, this site is the nucleus. Many viruses have evolved mechanisms that allow them to deliver their genome and accessory proteins through the nuclear pore complexes.

surface, thus enhancing entry and infection. Unlike receptors, however, they do not actively promote entry and mediate signals. Often, the interactions with attachment factors are not highly specific. In practice, the distinction between a receptor and an attachment factor is not always straightforward because the consequences of virus binding to a given surface component are difficult to assess experimentally and can vary depending on cell type and conditions.

Receptors and attachment factors constitute a diverse collection of proteins, carbohydrates, and lipids with physiologic functions unrelated to pathogen interaction. Ranging from abundant and ubiquitous to rare and species specific, they differ from one virus to the next. In the past few decades, an

impressive number have been identified in different virus and host cell systems. As shown in Table 4.1, which gives a partial list, receptors include ligand-binding receptors, glycoproteins, ion channels, gangliosides, carbohydrates, proteoglycans, and so on. Some families of surface molecules seem to be favored; the immunoglobulin-G superfamily of transmembrane proteins, proteoglycans, and glycoconjugates with terminal sialic acid residues, belong to these. In addition, a large group of viruses use integrins as their receptors.¹⁹⁰

Many viruses use multiple attachment factors and receptors. They interact with them in parallel or in series, or they use different receptors for entry into different cell types. When multiple receptors are required for productive entry, it is the convention to call the one contacted first a *receptor* and the subsequent ones *coreceptors*. A good example is human immunodeficiency virus type 1 (HIV-1), which makes use of heparan sulfate proteoglycans as attachment factors, CD4 as a receptor,²⁵ and CXCR4 and CCR5 (or a related chemokine receptor) as coreceptors.^{13,127} In this case, the two receptors are used to induce stepwise conformational changes in the spike glycoprotein. In other cases (e.g., adenovirus 2 and coxsackie B virus), two receptors seem to be needed to overcome anatomic and topological barriers.^{39,131} Herpes viruses are able to infect a variety of cell types, probably in part because they possess proteins that can bind to several different receptors.¹⁸⁵ Cases are also seen where unrelated viruses make use of the same receptors. One well-studied example is coxsackie and adenovirus receptor (CAR) (Table 4.1), which is used as a receptor both by adenovirus 2 and 5 and coxsackie B viruses.²¹⁹

The interaction between a viral surface protein and a receptor can be highly specific, but the affinity is often low. However, the presence of multiple, closely spaced binding sites on the surface of the virus particle allows multivalent binding, and the avidity is therefore frequently high. The affinity of influenza hemagglutinin for sialic acid containing glycoconjugates is, for example, in the millimolar range, but virus binding to cells is virtually irreversible.¹⁸⁰ That most receptor molecules are laterally mobile in the plasma membrane allows, moreover, the formation of a local *microdomain* rich in receptors under the bound virus with a composition and properties different from that in the surrounding membrane.⁵² The consequences can be the inclusion of the virus in lipid rafts, or entrapment in caveolae, coated pits, and other membrane specializations. Receptor clustering can also lead to transmembrane signaling, changes in the actin cytoskeleton, and recruitment of cytosolic factors such as a clathrin coat to the plasma membrane.

Although the interaction between a virus and its receptors is generally direct, there are cases where adaptor proteins are involved. For example, binding of antibodies to dengue virus allows infection of macrophages via Fc receptors on the surface of these cells.¹⁴³ In this case, the virus particle is internalized as an immune complex. Instead of neutralizing the virus, the antibodies mediate expansion of the host cell repertoire.

In enveloped viruses, the spike glycoproteins are responsible for receptor binding. Typically, these are oligomeric type 1 integral membrane proteins that have the bulk of their mass outside the membrane with the receptor-binding domain exposed. Other external domains in the same protein may be responsible for membrane fusion and receptor destruction. In some spike proteins (e.g., the HIV-1 glycoprotein), the receptor-binding moiety is not covalently connected to the rest, which allows its dissociation

TABLE 4.1 Receptor Proteins for Some Viruses

Virus	Family	Receptor	Function	References
G-protein-coupled receptors				
HIV	<i>Retroviridae</i>	CXCR4,CCR3,CCR2b,CCR8 CCR5	Chemokine receptors	2,32,47,163

once receptor interaction has occurred. X-ray crystal structures of spike glycoprotein–receptor complexes exist for several enveloped viruses (see Chapter 3).

In nonenveloped viruses, the structures that bind receptors are projections or indentations in the capsid surface. Adenoviruses have trimeric fiber proteins with globular knobs that project from the vertices.¹⁵ The penton base protein of many adenovirus subfamilies contains in addition an exposed Arg-Gly-Asp (RGD) sequence that associates with integrins.¹⁸⁹ Many enterovirus receptors bind in a cleft in the capsid surface called the *canyon*, the molecular features of which have been analyzed in great detail.¹⁶¹

ROLE OF CARBOHYDRATES

Glycoconjugates on the cell surface have an important role during entry of many viruses as receptors and attachment factors. Glycoproteins and glycolipids, with terminal sialic-acid residues, serve as specific receptors for a variety of viruses, including orthomyxo-, paramyxo-, and polyoma viruses. The HA1 subunits of influenza A virus hemagglutinin (HA) bind terminal sialic acid residues associated with galactose through either a Neu5Ac $\alpha(2,3)$ -Gal or Neu5Ac $\alpha(2,6)$ -Gal bond.¹⁸⁰ Human influenza recognizes the $\alpha(2,6)$ linkage; avian and equine viruses, the $\alpha(2,3)$ linkages, whereas porcine viruses appear to recognize both. These specificities reflect the structure of the glycans expressed in the different species and play a central role in limiting cross-species transmission. The tetrameric hemagglutinin-neuraminidase (HN) proteins of parainfluenza virus 5, has specificity for $\alpha(2,3)$ -sialyllactose,²¹⁸ and polyoma-viruses bind to specific saccharide residues in the glycan moieties of various gangliosides.²⁰¹ A difference limited to a single atom in sialic acids plays a major role in species specificity of simian virus 40 (SV40), because it binds better to the simian GM1 ganglioside, which has a *N*-glycolylneuraminic acid, than to the human, which has a *N*-acetylneuraminic acid.²³

The list of viruses recognized as binding to glycosaminoglycan (GAG) chains (e.g., heparan sulfate) is steadily growing.⁶ It now includes several herpes-, alpha-, flavi-, retro-, parvo-, picorna-, and papillomaviruses. Binding often involves positively charged patches in viral surface proteins. In some cases, viruses adopt GAGs as receptors when grown in tissue culture; their surface proteins mutate and express more basic residues.^{22,181} In contrast to tissue culture-adapted strains, natural isolates do not necessarily bind to heparan sulfate. Indeed, adaptation of different glycan receptors is likely part of the age-old war against pathogens, including viruses and their hosts, a war in which the diversity of surface carbohydrates plays an important role.

In most cases, it is the viruses that recognize host cell glycans. However, the reverse is true when cell surface lectins bind to glycans present in the envelope proteins of incoming viruses. One such lectin is DC-SIGN, a tetrameric, C-type lectin present on the surface of immature dendritic cells. It binds *N*-linked glycans of the high-mannose type,⁵⁷ such as in glycans that have failed to undergo terminal glycosylation in the Golgi complex of the infected cells. Because glycoproteins synthesized in insect cells have exclusively high-mannose glycans, viruses introduced into the skin via insect bites are often recognized by DC-SIGN, resulting in the infection of dendritic cells. Viruses that bind to these lectins include HIV-1, Sindbis, human cytomegalovirus, dengue, and severe acute respiratory syndrome (SARS) viruses.^{66,91,103,149,178,197} Thus cells that our body uses in the front-line defense against pathogens end up serving the interests of viruses instead of spreading the infection.

MOBILITY OF CELL-ASSOCIATED VIRUSES

The encounter between individual viruses and the cell can be visualized live by light microscopy using fluorescent viruses. What happens depends on the virus, the receptor, and the host cell. Parvovirus particles undergo rapid binding and release events that eventually result in permanent attachment and endocytic internalization.¹⁷¹ Polyomavirus particles bind firmly and diffuse laterally in the membrane for 5 to 10 seconds, after which they are arrested in confinement zones defined by the cortical actin network and eventually internalized.⁵⁴ Reoviruses do not show lateral motion after binding.⁵⁰ In the case of a bunyavirus, Uukuniemi virus, the rapid clustering of receptor molecules (GFP-tagged DC-SIGN) can be seen to occur at the site of virus binding.¹⁰²

Filopodia have been shown to play an active role by providing directed transport of surface-associated virus particles toward the cell body.⁹⁶ They are thin, mobile extensions of the plasma membrane stabilized by an actin filament bundle. Such “virus surfing” occurs at a rate of 1 to 2 $\mu\text{m}/\text{min}$, mirroring the rate of retrograde actin flow from the tip of the filopodia inward.¹⁶⁸ It is actin dependent and inhibited by inhibitors of myosin II. Although such motility of viruses is not essential for infection in tissue culture cells, it may play a role in tissues.

After endocytosis, the actin- and microtubule-dependent movement of intracellular vacuoles, viruses, and naked capsids inside the cell can also be visualized.^{50,77,95,164,207} This is illustrated by fluorescent influenza A viruses, which after a slow period of actin-restricted motion in the cell periphery, undergo rapid microtubule-mediated transport toward the perinuclear space where penetration by membrane fusion occurs.^{95,164} In

the case of adenovirus 2, the transport of capsids along microtubules is both plus- and minus-end directed, but net transport in the minus-end direction allows the virus to reach the nucleus.¹⁹³ The entry of parvovirus adeno-associated virus 2 has been traced all the way to the nucleus, inside of which it moves unidirectionally along well-defined pathways.¹⁷¹

VIRUS-INDUCED SIGNALS

Many viruses use the host cell's signaling systems to promote entry and optimize infection.^{68,124,131} Viruses take advantage of the fact that cells are exquisitely sensitive to ligands that bind to the plasma membrane, particularly if they induce clustering of surface components. More specifically, signaling is used to trigger access to coreceptors, to induce endocytic responses, to reprogram endocytic pathways, and to induce favorable intracellular conditions for infection.

Signaling starts at the plasma membrane after binding of the virus to receptors and formation of receptor clusters. Depending on the virus, receptors, and host cells, initial binding can lead to activation of tyrosine or other kinases, which, in turn, trigger cascades of downstream responses at the plasma membrane, in the cytoplasm, and, in some cases, in the nucleus. Virus-induced signaling depends on the usual panel of second messengers (phosphatidylinositides, diacylglycerides, and calcium), and on numerous regulators of membrane trafficking and actin dynamics.

One well-studied case that demonstrates the complexity of virus-induced signaling is provided by adenoviruses 2 and 5, which use CAR and integrin $\alpha\beta 3$ as receptors.^{68,131} Endocytic internalization occurs via clathrin-coated vesicles, and penetration takes place in endosomes. The interaction with the integrin triggers activation of p85/p110, a PI(3) kinase. The synthesis of PI(3,4)P₂ and PI(3,4,5)P₃ activates protein kinase C. Small GTPases (e.g., Rab and Rho family members) are also activated. One of the downstream responses is the transient activation of macropinocytosis, an actin-dependent process that results in a rapid increase in internalization of fluid.¹¹⁸ This response seems to promote subsequent penetration of adenovirus from endocytic vacuoles by virus-induced rupture.

Another example is SV40, which is entirely dependent on signaling for entry. After binding to GM1 gangliosides, the virus induces local activation of tyrosine kinases, which results in actin filament reorganization, activation of caveolar dynamics, internalization of the virus in caveolar or lipid raft vesicles, and induction of long-distance transport of the virus-containing vesicles.^{44,135,145,187} More than 50 different kinases were shown to regulate the entry and early steps in the infection of HeLa cells by this virus.¹⁴⁴

A final example involves Kaposi's sarcoma-associated herpesvirus (human herpesvirus 8).²⁸ The glycoprotein gB of this virus possesses an RGD sequence in the ectodomain that allows it to bind to the integrin $\alpha 3\beta 1$. Binding activates focal adhesion kinase (FAK) and Src kinases, which, in turn, activate PI(3) kinases and Rho GTPases. Furthermore, via the PI(3) K-PKCzeta-mitogen activated or extracellular regulated kinase (MEK) pathway, the virus induces the extracellular signal-regulated kinase 1 and 2 (ERK1/2). Activation of these pathways leads to major alterations in the actin cytoskeleton, and the virus is internalized by macropinocytosis in human fibroblasts.

ENDOCYTIC PATHWAYS OF INFECTION

Whether viruses penetrate into the cytosol directly through the plasma membrane or after endocytosis has been a hotly debated issue from the beginning of animal virology. It is now recognized that a majority of animal viruses—whether enveloped or nonenveloped—make use of endocytosis for productive infection. They exploit one or more of several endocytic mechanisms offered by cells (Fig. 4.2), and most of them enter endocytic vacuoles where penetration into the cytosol occurs often triggered by low pH. Enveloped virus families (e.g., paramyxoviruses, herpesviruses, and retroviruses) that can penetrate directly through the plasma membrane because they do not require endocytosis for fusion may still depend on endocytosis for productive infection at least in some cell types.^{92,133} Here, the reason may be that fusion at the plasma membrane remains nonproductive because it does not ensure passage of the capsids through further barriers such as the actomyosin cortex.¹⁰⁸

The main reason why endocytosis is a preferred mode of entry is most likely that endocytic vesicles offer viruses a free ride through the cortical cytoskeleton and other barriers that encumber movement of virus-sized particles in the cytoplasm. By delaying their penetration, viruses can in this way get a ride to the perinuclear region of the cell. In endocytic vacuoles, viruses can, moreover, count on receiving specific cues such as a drop in pH and exposure to proteases to trigger penetration

FIGURE 4.2. Mechanisms of endocytosis used for virus entry. Viruses can use different mechanisms of endocytosis. The majority of animal viruses enter cells by endocytosis. The mechanisms include (A) clathrin-mediated endocytosis, the most commonly used mechanism for virus entry; (B) caveolar endocytosis, a caveolin and lipid raft-dependent mechanism mainly used by polyomaviruses; (C) a caveolin-independent, lipid raft-mediated mechanisms with many similarities to the caveolar mechanism; (D) various caveolin- and clathrin-independent mechanisms often with similarities to macropinocytosis; and (E) macropinocytosis, a transient, ligand-induced, actin-dependent mechanism.

and uncoating. Because no trace of the virus is left exposed on the plasma membrane, immunorecognition of infected cell is delayed. Moreover, for nonenveloped viruses that use membrane lysis or pore formation for penetration, it may be essential to cross membranes of intracellular organelles to minimize damage to the cell.

In recent years, the landscape of endocytosis research has expanded dramatically beyond phagocytosis and the classic clathrin-mediated endocytosis pathway. New mechanisms include caveolar or lipid raft-mediated endocytosis, macropinocytosis, and several other clathrin- and caveolae-independent pathways (Fig. 4.2).^{46,116,123,141,203} The situation is often confusing because the mode of uptake of a virus can vary between cell types and strains, and many viruses can make use of multiple receptors and parallel routes of endocytosis in the same cell. In addition to caveolae, SV40 can, for example, utilize a related, noncaveolar pathway.⁴⁴ Influenza A uses both clathrin-mediated and clathrin-independent pathways,^{112,164,175} and HIV-1, which can fuse with the plasma membrane, can in some cell lines also make efficient use of an endocytic pathway for entry.⁴² The use of multiple receptors and redundant endocytic pathways provides viruses with a degree of flexibility and adaptability that make entry a difficult step for host organisms to protect themselves against.

The cell biology of endocytosis and its regulation is complex.^{35,98} Not surprisingly, the analysis of virus entry by high throughput siRNA silencing screens have led to the identification of hundreds of genes involved as critical factors in early infection of tissue culture cells.^{31,79,144} Entry studies are often further complicated by the fact that only a small fraction of the cell-associated viruses enter productively. Because most morphological and biochemical methods fail to distinguish between particles that enter productively and those that do not, studies using these methods must be complemented with readouts based on infection (i.e., the biological outcome of successful entry). This involves the use of inhibitors, dominant negative mutants, small interfering RNAs, mutant viruses, and mutant cell lines. Only a combination of methods allows pathways of productive entry to be charted with confidence.

CLATHRIN-MEDIATED ENDOCYTOSIS

The clathrin-mediated endocytic pathway is used by many viruses (Figs. 4.2 and 4.3). It is a process that cells use to internalize a spectrum of receptor-bound ligands, fluid, membrane proteins, and lipids for recycling or degradation. By binding to receptors that have the internalization signals necessary for inclusion in clathrin-coated pits, viruses make use of this pathway as opportunistic ligands. Uptake is characterized by rapid kinetics (viruses are generally internalized within a few minutes after binding) and by high capacity (3,000 virus particles or more per minute).¹⁰⁹ With a diameter up to 120 nm, coated vesicles are large enough for the endocytosis of most animal viruses. Sometimes larger particles (e.g., vesicular stomatitis virus [VSV]) can be accommodated.¹¹³

Although clathrin-mediated endocytosis is a continuously ongoing process, it is under stringent control. Interestingly, when the uptake of VSV, influenza, and reovirus particles has been followed in live cells, it has been observed that most are

internalized by clathrin-coated pits that form *de novo* under the virus particles.^{41,85,164} Only a few enter via pre-existing clathrin-coated pits. Exactly how the virus induces a transbilayer signal to direct the assembly of the clathrin coat remains to be defined.

A role for clathrin-coated pits in internalization and infection can be demonstrated by inhibiting clathrin function using dominant negative mutants or depletion of adaptors such as epsin, eps15, AP2, or the clathrin chains themselves.^{37,175} Inhibition of dynamin 2, a scission factor in clathrin vesicle formation, is not a sufficient indicator for clathrin involvement because dynamin 2 is also involved in other forms of endocytosis.

MACROPINOCYTOSIS

Among the clathrin-independent mechanisms, macropinocytosis and related processes are commonly used by larger viruses such as vaccinia, herpes, adeno 3, and Ebola virus, but evidently also in some cases by smaller viruses such as HIV-1 and influenza A.^{4,87,107,122,165} Macropinocytosis is ligand triggered, transient, actin dependent, and regulated by a complex signaling pathway.^{123,194} The physiological cargo is mainly composed of extracellular fluid that is trapped in large vacuoles, the formation of which depends on plasma membrane ruffling. The process differs from phagocytosis in the signaling pathways used and in that it can be activated in most cell types, not only in specialized cells.¹⁹⁴ In addition, by serving as a major mechanism in the elimination of apoptotic debris in tissues, macropinocytosis differs from phagocytosis by failing to activate innate immune responses and inflammation.

In macropinocytosis, the interaction of viruses with the plasma membrane induces a rapid activation of receptor tyrosine kinases or integrins. This leads to a signaling cascade that usually involves the activation of GTPases Rac1 or cdc42, the p21-activated kinase (PAK1), myosin II, and numerous other kinases and signaling factors.¹²³ A change in the dynamics of cortical actin leads to ruffling of the plasma membrane, where the ruffles can take the form of lamellipodia, filopodia, and blebs. In the case of vaccinia virus and Kaposi's sarcoma virus, internalization by macropinocytosis occurs during bleb retraction, and the viruses enter macropinosomes from which they escape by membrane fusion.^{122,202} As more is learned about the mechanisms underlying macropinocytosis, it is becoming increasingly clear that there are variations of the general themes. Differences between cell lines and signaling pathways lead to a complex spectrum of related activities.

CAVEOLAR AND LIPID RAFT-MEDIATED ENDOCYTOSIS

The caveolar and lipid raft-mediated pathways of endocytosis were first observed for SV40 and mouse polyomavirus^{3,44,158,187} (Figs. 4.2 and 4.3). They are cholesterol dependent, tyrosine kinase activated, cargo induced, and involve small endocytic vesicles. The cholesterol dependence reflects a central role of lipid rafts. Three variants of caveolar or lipid raft endocytosis are currently recognized⁹⁴: (a) endocytosis via classical caveolae, dynamin 2 dependent; (b) noncaveolar, lipid raft-mediated

FIGURE 4.3. Electron microscopy of virus endocytosis. **A:** A surface replica of a BHK21-cell with Semliki Forest virus (SFV) particles attached. Some particles are bound to microvilli, and one is about to be endocytosed inside a coated vesicle (Courtesy of J. Heuser and A. Helenius). **B:** Internalization of a SV40 particle by caveolar- or raft-mediated endocytosis. The tight fitting vesicle in which the virus is internalized has a diameter of about 60 to 70 nm, and it has no visible coat (Courtesy of J. Kartenbeck and A. Helenius). **C:** SFV particles in clathrin-coated vesicles (Courtesy of *J Cell Biol*). **D:** SV40 particles in an early endosome. **E:** Incoming SV40 particles in a smooth membrane section of the endoplasmic reticulum, which they reach via the endocytic pathway. (From Kartenbeck J, Stukenbrok H, Helenius A. Endocytosis of simian virus 40 into the endoplasmic reticulum. *J Cell Biol* 1989;109(6 PE1): 2721–2729, with permission.)

endocytosis, dynamin 2 dependent; and (c) noncaveolar, lipid raft-mediated endocytosis, dynamin independent.

Caveolae constitute 70-nm flask-shaped indentations that contain caveolins and cavins as major protein components and a membrane enriched in cholesterol and sphingolipids.^{141,156} Most cell surface caveolae are stationary, with a minority population undergoing a local cycle of fission and fusion with the plasma membrane.^{146,204} When local tyrosine phosphorylation is activated by a virus such as SV40, caveolae become more dynamic.^{94,141}

With a virus particle trapped inside, the caveolae pinch off and move into the cytoplasm where they fuse with endosomes.

SV40 and other polyomaviruses also enter in vesicles devoid of caveolar proteins.⁴⁴ After association with lipid rafts in the plasma membrane or artificial liposomes, the binding of SV40 to multiple receptor gangliosides, GM1, leads to the induction membrane curvature following the shape of the virus and the formation of tight-fitting indentations of variable depth.⁵³ For detachment of a vesicle, these inward-oriented,

FIGURE 4.4. The endosomal pathway. The pathway functions as two interconnected cycles of membrane trafficking. One involves the plasma membrane, early endosomes, and a variety of carrier vesicles. Its major role is the sorting and recycling of incoming membrane components, ligands, and fluid via the endosome back to the cell surface. In this pathway, the pH does not drop below about 6.0, and the cargo is not exposed to a spectrum of lysosomal enzymes. The main function of the second cycle, the lysosome cycle, is degradative (i.e., the down-regulation of receptor-ligand complexes, degradation, and processing of incoming nutrients and their carriers, digestion of autophagic substrates, elimination of incoming pathogens, etc.). The endocytic cargo to be degraded, including viruses, is sorted from early endosomes into late endosomes, and these deliver the cargo to lysosomes 10 to 40 minutes after formation by fusing with them to form endolysosomes. The late endosomes undergo a complex maturation process, acquire intraluminal vesicles, and move along microtubules to the perinuclear region of the cells. Degradation occurs in the endolysosomes through the action of soluble hydrolases. Endolysosomes and lysosomes keep fusing with new late endosomes in a continuous cycle. Early and late endosomes communicate via vesicle trafficking with the Golgi complex, and late endosomes and endolysosomes have a poorly understood connection to the endoplasmic reticulum.

virus-containing “buds” require the activation of kinases and other cellular factors. The process shares many features with the endocytic mechanism triggered by certain bacterial toxins, such as shiga and cholera.¹⁶⁰

THE ENDOCYTIC PATHWAY

The early endosomes in the periphery of the cytoplasm receive incoming viruses a few minutes after internalization (Figs. 4.4 and 4.5). Early endosomes constitute complex, heterogeneous organelles with tubular and vacuolar elements. They are mildly acidic (pH 6.6 to 6.0), which is enough to activate viruses with a high pH threshold for penetration, and these viruses are thought to penetrate from early endosomes.¹¹⁰ Most viruses are not activated in this pH range and continue deeper into the degradative arm of the endocytic pathway in order to penetrate from late endosomes or endolysosomes. In exceptional cases, such as some of the polyomaviruses, viruses continue even farther, using a poorly characterized transport system that brings them to the endoplasmic reticulum (ER).^{51,152} Their penetration occurs through the ER membrane. In the case of macropinocytosis, the penetration is likely to occur in macropinosomes, but there is not much information available about macropinosome maturation and fate.

To understand virus entry, it is important to understand the cell biology of endosomes. There are numerous reviews that provide insights into this important topic.^{63,73,120,166,170} One of the central topics is the maturation of late endosomes, a program

of changes that prepares them for fusion with lysosomes.⁸² The changes include a further drop in pH, a switch of predominant Rabs from Rab5 to Rab7, a switch from phosphatidylinositides (PI(3)P to PI(3,5)P₂, exchange of tethering factors for fusion, exchange of microtubule-dependent motors, formation of intraluminal vesicles, and accumulation of lysosomal membrane proteins and hydrolases. It is a complex process where the various alterations are coordinated and interdependent. The key factors include small GTPases of the Rab, Arf, and Rho families and their effectors, phosphatidylinositides and their kinases and phosphatases, protein ubiquitination and the endosomal sorting complex required for transport machinery responsible for the formation of intraluminal vesicles in endosomes, the vacuolar ATPase responsible for acidification, and various soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors and tethering factors required for selective fusion events.

Late penetrating viruses such as influenza virus, minor group rhinoviruses, polyomaviruses, and bunyaviruses depend on a smoothly functioning maturation program. They require the formation of late endosomes, the reduction in pH, and transport of the endosome to the perinuclear region.^{63,72,101,174} Infection can be blocked by interfering with the maturation program using inhibitors, dominant negative mutants, and siRNA depletion of endocytosis factors.

The significance of low pH in endosomes as a cue for the activation of virus penetration was discovered a long time ago.⁷⁶ It is now clear that for the majority of animal viruses, low pH is needed to trigger conformational changes in metastable viral particles and fusion proteins, thus activating membrane

FIGURE 4.5. Viruses enter endosomes. Endosomes are cytoplasmic vacuoles with complex and quite heterogeneous morphology. Thin section electron microscopy reveals that many of them are filled with intracellular vesicles and membrane lamellae. **A:** Influenza A viruses (arrow heads) are here seen in multivesicular endosomes closely connected to microtubules. **B:** Human papilloma-16 pseudovirus particles are here seen in an endosome with tubular extensions. (Courtesy of Roberta Mancini.)

penetration mechanisms (see Chapter 3). Viruses with a relatively high pH threshold (pH 6.5 to 6.0) such as VSV are activated 3 to 10 minutes after internalization in early endosomes.¹⁰⁹ Viruses with a lower pH threshold are sorted from early endosomes into the degradative branch and penetrate later (10 to 50 minutes or even longer after infection) and less synchronously in late endosomes or endolysosomes that have a pH of 6.0 to 4.9. For example, influenza A virus, with a pH threshold of 5.6 to 4.9, passes via early endosomes to perinuclear late endosomes before membrane fusion and penetration occurs.¹⁷⁶

PENETRATION BY MEMBRANE FUSION

The membrane of an enveloped virus is a *de facto* transport vesicle designed for intercellular membrane traffic (Fig. 4.6).

Like intracellular transport vesicles, the transport process relies on budding, fission, and fusion. The cargo is the viral capsid, which does not have to cross the hydrophobic barrier of a membrane. The fusion reaction during entry can occur with the plasma membrane or with the limiting membrane of an endosome. On the basis of studies with VSV, it has been proposed that a virus can also fuse with luminal membrane vesicles inside multivesicular endosomes followed by a delayed second fusion event between the vesicle and the limiting membrane of late endosomes.^{72,162} The second fusion would have to depend on a cellular rather than viral fusion machinery.

As described in Chapter 3, viral fusion proteins are integral membrane proteins, with the bulk of their mass external to the viral envelope. They are usually glycoproteins and occur as homo- or hetero-oligomers. Many of them combine fusion and receptor-binding activities in the same molecule. To become

FIGURE 4.6. Enveloped viruses use a vesicle shuttle mechanism. They transport the capsids and the viral genome from cell to cell using a vesicle transport strategy based on membrane fission and fusion. The viral envelope constitutes the transport vesicle, and the capsid is the cargo. The vesicle is formed after capsid loading and glycoprotein sorting in the infected cell by budding and membrane fission at the plasma membrane or internal membranes. The viral envelope membrane protects the capsid during the voyage through the extra cellular space. After associating with a new host cell, the virus delivers the capsid into the cytosol by membrane fusion, either at the plasma membrane or after endocytosis, at the limiting membranes of intracellular organelles. The advantage of this strategy is the viral genome, and accessory proteins can be transferred from cytosol to cytosol without the need of translocation directly across the hydrophobic barrier of any membrane.

fusion competent after folding and assembly in the ER, they are often primed by proteolytic cleavage during transit through the trans-Golgi network (TGN). Typically, the proteases responsible for priming are furin family convertases that cleave either the chains involved in fusion directly (i.e., in myxo-, retro-, and paramyxoviruses) or the companion proteins in the spike protein complex (i.e., alpha- and flaviviruses).^{90,186,208} If virus assembly and budding occurs intracellularly, as for flaviviruses, the activating cleavages take place as the assembled viral particles pass through the TGN.⁷⁵ In some cases, such as Ebola virus, proteolytic activation can occur as part of the entry program by proteases present in endocytic vacuoles.³⁰

Proteolytic priming renders fusion proteins metastable and, thus, competent to undergo large, irreversible conformational changes without added energy.²⁷ This is important because, to elicit fusion, they must undergo changes that dramatically alter their quaternary or tertiary structure. As a result, they expose previously hidden hydrophobic peptide segments (fusion peptides) that interact with the target membrane, and in doing so allow the proteins to be hydrophobically anchored in both membranes.²¹⁰ The conformational change is thought to provide the energy required to overcome the so-called *hydration force* that prevents biological membranes from fusing spontaneously.¹⁵⁵

The changes in conformation are triggered either by low pH in endosomes or by interaction between viral proteins and receptors in the plasma membrane. Sometimes receptor binding followed by low pH is needed. This type of receptor-mediated priming, observed for some retroviruses,¹²⁸ may allow the virus particle to limit conversion of spike glycoproteins to the site most intimately in contact with the target membrane. The priming and activation of viral membrane fusion proteins as well as the mechanisms of fusion are discussed in greater detail in Chapter 3.

PENETRATION BY NONENVELOPED VIRUSES

Nonenveloped viruses penetrate into the cytosol through the limiting membranes of internal organelles (e.g., endosomes, lysosomes, the ER). The cues that trigger penetration are similar to those used by enveloped viruses (e.g., receptor-binding, low pH, redox environment). These viruses must, however, transfer their capsids, genomes, and associated proteins through a cellular membrane without the convenience of the membrane-fusion mechanism.

The mechanisms involved have proved challenging and remain incompletely understood. It seems, however, that non-enveloped viruses can use three general strategies:

- (a) *Membrane puncture.* The virus particle generates a pore in the membrane through which the genome is selectively released into the cytosol. The viral capsid does not enter the cytosol, and release of fluid phase markers from the lumen of the organelle is either undetectable or limited to small molecular weight compounds.
- (b) *Perforation.* The entire capsid is transferred through the membrane without major lysis of the membrane and little loss of luminal fluid markers.
- (c) *Lysis.* The virus particles induce breakage of the membrane of cytoplasmic organelles, allowing the virus and other luminal contents to be released into the cytosol.

The puncture or pore mechanism is favored for picornaviruses.^{64,81} Some rhinoviruses and foot-and-mouth disease virus are acid-activated and penetrate from endosomes, whereas others (e.g., polio, coxsackie B, and echovirus 1) are pH independent but penetrate from endosomes or other intracellular organelles. In the case of poliovirus, which is one of the best characterized, penetration is induced by binding of a cluster of poliovirus receptor (PVR) molecules to “canyons” in the capsid surface. This triggers a large, concerted, irreversible change in the particle, the so-called *eclipse*, which leads to the formation of a penetration competent conformation. An internal protein, VP4, is released, and the myristylated *N*-terminus of VP1 inserts into the endosomal membrane.^{16,61} The RNA is most likely released to the cytosolic side of the membrane through a narrow pore.¹⁹⁹ According to this view, penetration and uncoating occur simultaneously, and the capsid does not enter the cytosol. Recently, cryo-electron microscopy (cryoEM) studies have shown that one of the icosahedral vertices interacts with five receptors that connect the modified particle intimately with the membrane.¹⁹

Adenoviruses make use of a lytic mechanism.¹⁷² The best studied are adenoviruses 2 and 5, which penetrate by acid-activated rupture of the endosomal membrane.^{117,119} The lytic effect is thought to involve a change in the penton base and exposure of an amphipathic helix in protein VI, but the mechanism is unclear.¹³⁰ Altogether, the process is complex; it depends on low pH, the integrin receptors, cleavages in structural proteins induced by the L3/p23 viral protease, the release of fiber proteins, activation of macropinocytosis, and signaling through protein kinase C.^{117,119,131}

For parvoviruses, evidence is accumulating that the *N*-terminal domain of VP1 possesses a phospholipase 2 domain activated by low pH.^{38,74} It is likely that this promotes membrane penetration of the intact virus by modifying the permeability of endosomal and lysosomal membranes. Lysis of the membrane is not detected.

INTRACELLULAR TRAFFICKING

Before they can replicate, viruses and capsids delivered into the cytosol must be transported to the correct location before uncoating and replication can take place. Within the nucleus, replication usually occurs in defined foci. In the cytosol, it is often associated with specific membrane organelles (e.g., the ER or the ER-Golgi intermediate compartment) or with virus factories in the perinuclear space.^{136,215}

Given the extreme crowding in the cytoplasm that prevents diffusion of virus- and capsid-sized particles as well as uncondensed forms of DNA or RNA, it is not surprising that viruses rely on cytoplasmic transport systems offered by the cell.^{45,70,105,182} For long-distance transport, viruses mainly exploit microtubule-mediated mechanisms. When actin filaments play a role, it is usually in short-distance movement close to the plasma membrane. Although viruses can undergo partial disassembly *in transit* through the cytosol, they postpone final uncoating of the condensed genome until they have reached their final destination. Viruses travel variable distances. To reach the cell body, neurotropic viruses that enter via axons may have to move in a retrograde direction over the full length of axons, which can be more than 1 m in length.

To move through the cytoplasm, incoming viruses have two options. They can postpone penetration into the cytosol and move as cargo in endocytic vesicles and thus benefit from the motor-driven transport of vesicles and organelles through the cytoplasm. Alternatively, they can penetrate early into the cytosol, in which case the viruses or their capsids are themselves responsible for associating with molecular motors and adaptors (e.g., dynein and kinesins). The former strategy is used by viruses that enter by endocytosis, the latter by viruses that prefer to penetrate through the plasma membrane. Many viruses make use of both; part of the journey is mediated by vesicular traffic, the rest by cytosolic transport. Thus, viruses (e.g., adeno- and parvoviruses) that enter by endocytosis have been shown to use microtubule-mediated transport after penetration into the cytosol.^{171,192,193} Although transport of capsids along microtubules is often bidirectional and characterized by stops, restarts, and changes in direction, net transport generally occurs in the minus-end direction toward the microtubule organizing center, where viruses and capsids are often found to accumulate before transport to the nucleus.¹⁵⁴ Whether they switch to plus-end directed motors for the final leg of transport is not known.

UNCOATING

The entry of viruses includes partial or full disassembly as an essential, integrated part of the program. For enveloped viruses, uncoating involves loss of the envelope during membrane fusion. Often, the capsid thus released undergoes further step-wise uncoating steps. Once the capsids have reached the correct location within the cell, then, and only then, they release the replication competent form of the genome. In some cases (e.g., retro-, reo-, and poxviruses), the cytosolic capsids serve as a protected site for reverse transcription of the genome or transcription of messengers following entry into the cytosol.^{88,134}

In the case of nonenveloped viruses, the uncoating process involves conformational changes, progressive loss of structural proteins, proteolytic cleavages, isomerization of intermolecular disulfide bonds, and weakening of intermolecular interactions.^{69,81,117,132,169} For adenovirus 2, disassembly starts already at the cell surface with loss of some of the fibers followed by activation of a viral protease (the L3/p23 protease, located within the virion), proteolytic cleavage of capsid proteins, and loss of stabilizing capsid components. Final disassembly of the particle and DNA release occurs at the nuclear pore complex (NPC).

The conformational changes that accompany penetration and uncoating of polio and other picornaviruses have been extensively analyzed.^{64,81,100} Depending on the virus, the initial uncoating event is triggered by receptor association, low pH, or both. Conversion from a 150S to 160S particle to a slower sedimenting 135S particle occurs with elimination of the internal VP4 protein and externalization of the myristylated *N*-terminus of VP1. This leads to membrane association, followed by the release of the RNA, resulting in the RNA-free 80S particle. The single-stranded viral RNA is likely to escape through one of the 12 vertices, possibly aided by the VPg protein covalently linked to the 5' end of the viral RNA.^{18,89}

The capsids of viruses with a double-stranded RNA genome (e.g., reoviruses) undergo many alterations in transit into the cell, but instead of releasing their genomic RNA in free

form into the cytosol, they retain it in a modified capsid, which serves as an RNA-replication and transcription factory.^{29,177}

TRIGGERING THE UNCOATING PROGRAM

Penetration brings many viruses and viral capsids for the second time into a cytosolic environment. The first time is when they assemble in the cytosol of an infected cell or when they pass through the cytosol on their way from the nucleus to the extracellular space. During entry into a new host cell, the agenda involves disassembly and uncoating instead of assembly. This means that, in the entry phase, something must be profoundly different either about the virus itself or the cell.

Usually, the difference is in the virus or the capsid because it has undergone structural alterations *in transit*. After release from the infected cell or during earlier stages of entry, the viruses are structurally *reset* so they can respond to cellular cues according to requirements of the uncoating program. The best illustration of this is provided by retroviruses, in which the viral protease induces a series of cleavages in Gag and Gag-Pol proteins during and after virus budding. The capsid is reorganized and ready for reverse transcription and for the formation of functional preintegration complexes (PICs) in the cytosol of a new target cell.¹³⁴

Another example is influenza A, in which the switch involves a change in the properties of the matrix protein (M1). M1 serves as an adaptor between the virus ribonucleoproteins (vRNPs) and the viral membrane as well as between the vRNPs, and it plays a crucial role during assembly of these components during virus assembly and budding.^{157,220} During entry, dissociation of these interactions is induced by an irreversible conformational change in M1 triggered by acid exposure in endosomes.²⁰ To acidify the internal space of the virus, where the M1 and the vRNPs are located, the viral membrane possesses acid-activated proton channels in the form of M2 protein complexes.^{148,191} If the M2 proton channel is blocked using amantadine, a specific M2 channel blocker used as an anti-influenza drug; HA-mediated fusion occurs normally in endosomes, but the vRNP and M1 fail to dissociate from each other, and transport of vRNP to the nucleus is inhibited.^{21,111}

Alphaviruses seem to use an altogether different strategy. Here the *switch* seems to involve a change in the cell rather than in the viral capsid. A cellular factor required for uncoating of incoming capsids is inactivated during the course of infection, thus allowing assembly of progeny capsids. The factor in question is the 60S ribosomal subunit, which has high affinity binding sites for the viral capsid protein.^{179,209} Incoming capsids rapidly lose capsid proteins to ribosomal subunits, and the viral RNA is thus liberated. When synthesis of structural protein starts later in an infection, newly synthesized capsid proteins bind to the ribosomal subunits and the ribosomal subunits can no longer interfere with assembly of progeny capsids.

NUCLEAR IMPORT

Most DNA viruses and a few negative-stranded RNA viruses replicate in the nucleus. To enter the nucleus, they can make use of the NPC for transport of the genome and accessory proteins into the nucleoplasm.^{34,40,69,211,212} (Fig. 4.7). Alternatively, the viruses may enter by rupturing the nuclear envelope, a process for which there is some evidence in the parvovirus field. These

FIGURE 4.7. Import of viruses and subviral particles through the nuclear pore complex. To circumvent the size limitation (diameter 35 to 40 nm) of particle transport through the nuclear pore complex (NPC), viruses have evolved different strategies. **A:** The genome of a virus can be divided in multiple subgenomic particles with an elongated shape thin enough for individual entry (e.g., influenza virus). **B:** Limited uncoating takes place in the cytosol with the generation of an opening in the capsid wall that allows the DNA to escape, leaving an empty capsid at the NPC (e.g., herpes simplex virus 1). **C:** The virus disassembles after association with the NPC, allowing the genome and accessory proteins to pass through the NPC (e.g., adenoviruses). **D:** The virus particles or capsids are small enough to enter as spherical particles without uncoating or major deformation with uncoating occurring in the nucleoplasm.

two entry routes allow infection of nondividing, terminally differentiated, interphase cells in which the nuclear envelope represents a permanent barrier. Finally, viruses and viral capsids may wait in the cytosol for the dissolution of the nuclear envelope during cell division. This mechanism is used by most retroviruses with the exception of lentiviruses (and possibly papilloma viruses)¹⁵¹ and restricts infection to cell populations that undergo division. In principle, a fourth possibility would be penetration directly from the lumen of the ER through the inner nuclear membrane because the lumen of the ER is continuous with the space between the membranes in the nuclear envelope. Although some incoming viruses do pass through the ER and incoming viral particles have been occasionally seen between the two membranes of the nuclear envelope,¹¹⁴ no evidence currently indicates that any viruses use this pathway.

Nuclear import via the NPC involves several steps: binding of import receptors, transport through the cytosol, association with the NPC, and transfer of the intact virus, a subviral complex, or a nucleic acid through the pore. To be recognized by the cellular import machinery, viruses and viral capsids make use of nuclear localization signals (NLSs) similar to those present on cellular proteins and ribonucleoprotein complexes. These signals in viral proteins are recognized by soluble receptor proteins (importins or karyopherins) that mediate recognition, transport, and docking of the viral capsids to the NPC. In some cases, the NLS and the importins involved have been identified. Exposure of the NLS is sometimes modulated by phosphorylation-induced conformational modifications to avoid premature capsid import in the infected cell,⁸⁶ and some viruses are thought to be processed by proteasomes.²⁰⁶ It is also possible that viruses bind directly to the NPC without interaction with importins. This seems to be the case for adenovirus 2, which binds directly to the CAN/Nup214 nucleoporin.²⁰⁰

The size limitation for transport through the NPC is an obvious problem. Although estimates of the functional pore diameter have been adjusted upward to 39 nm,¹⁴⁰ only the smallest viruses and capsids are likely to enter intact without modifications. These include parvoviruses and the capsids of hepatitis B virus (HBV).^{153,206} When nuclear import of injected HBV capsids through the NPC are imaged by electron microscopy, the capsids can be seen to line up on the cytosolic fibers of the NPC and inside the central channel (Fig. 4.8). Uncoating of these capsids occurs in the basket, a structure located on the nucleoplasmic side of the NPC.¹⁵³

Being too large, most viruses and capsids must undergo shape changes or disassembly before passage of the genome through the NPC. Partially uncoated and modified adenovirus 2 particles bind to the CAN/Nup214 nucleoporins on the outer surface of the NPC, where they break apart, releasing the linear, double-stranded viral DNA for transport through the NPC.²⁰⁰ A histone protein, H1, has been implicated as a disassembly factor and a trans-NPC *guide* for the released DNA.

Binding of herpes simplex virus capsids to the NPC is mediated by capsid and tegument proteins.^{139,142} After association with CAN/Nup214 and another NPC protein, hCG1, through the minor capsid protein pUL25, and after opening of the portal structure at one of the vertexes of the capsid, the viral DNA escapes into the nucleus, leaving an empty capsid behind at the mouth of the NPC (Fig. 4.9). Influenza A viruses deal with the problem of size limits by having a segmented

FIGURE 4.8. Herpes simplex virus 1 (HSV-1) entry at the plasma membrane level and the nuclear envelope. **A:** In HSV-1, virus can fuse with the plasma membrane and release the capsid and the tegument into the cytosol. A large part of the tegument can be seen separating from the capsid. **B:** After binding to the cytosolic fibers attached to the nuclear pore complex (NPC), the viral capsid releases its DNA genome through one of the pentameric facets, and an intact-looking empty capsid shell remains bound to the NPC for some time. PM, plasma membrane; NE, nuclear envelope. Space bar, 100 nm. (Courtesy of B. Sodeik and A. Helenius.)

FIGURE 4.9. Import of hepatitis B virus (HBV) capsids through the nuclear pore complex (NPC). After injection into *Xenopus oocytes*, isolated HBV cores can be seen binding to fibers at the mouth of the NPC, and to line up in a row inside the channel of the pore. Uncoating of this capsid occurs in the basket on the nucleoplasmic side of the NPC. (Courtesy of N. Pante and M. Kann.)

genome. The eight subgenomic RNA are individually packaged into viral vRNP complexes. When interactions with the M1 protein are dissociated after exposure of the virus to low pH in endosomes, the vRNP can interact with importins, travel to the nucleus, and enter individually through the NPC (Fig. 4.7).^{20,111,138} The vRNPs are rod shaped and, although variable in length, have a thickness of only 10 to 20 nm.³⁶

The PIC of retroviruses has been reported to be about 50 to 60 nm in diameter.¹²⁶ Too big to enter the nuclei without conformational adjustments, they remain in the cytosol until the breakdown of the nuclear envelope occurs during cell division.⁹⁷ Being capable of entering interface nuclei, the PIC of HIV-1 and other lentiviruses are exceptions. The details of how and in which form lentivirus PICs are imported into the nucleus remain controversial.

TRANSMISSION DIRECTLY FROM CELL TO CELL

Discussion so far has focused on the mechanisms of entry by free viral particles attaching to the surface of cells. It is increasingly clear that there are situations in which infection occurs from cell to cell without participation of free virus particles^{129,167} (Fig. 4.10). One mechanism involves fusion of an infected cell's plasma membrane with the membrane of a neighboring cell. In infected tissues and cultures, the result is the formation of multinucleated cells (i.e., syncytia). Fusion in this case is mediated by viral fusion proteins expressed on the surface of the infected cell with receptors present on the noninfected cell. Commonly observed with paramyxovirus, herpesvirus, and other viruses with pH-independent fusion proteins, cell

FIGURE 4.10. Direct cell-to-cell transmission. Several mechanisms allow infection to be transmitted via cell contacts without the release of free virus particles into the extracellular space. **A:** Due to the presence of viral fusion proteins on the surface of the infected cells and virus receptors on the noninfected cells, fusion of two cells can occur without producing virus particles. This results in the formation of syncytia. This mechanism is often seen with enveloped viruses and with fusion proteins that do not require low pH for fusion. **B:** In the case of poxviruses, extracellular viruses belonging to the so-called extracellular class of virions remain attached to the surface of the infected cell, where they trigger the formation of a motile, actin-containing, extension of the plasma membrane. This extension is thought to promote contact of the virus with the surface of a neighboring cells. **C:** The infected cells can undergo polarization so that progeny viruses are selectively released into a region of the cell periphery intimately in contact with another cell. Such specialized regions are called virological synapses.

fusion provides a mechanism for transmitting infection independently of virus particle assembly.³³

Other mechanisms of cell-to-cell transmission require the formation of virus particles, but these are not released freely into the extracellular space. Poxviruses such as vaccinia virus generate infectious particles called external enveloped viruses, most of which not only remain attached to the cell surface after formation, but also induce the formation of a motile surface extensions through the polymerization of actin inside the cytoplasm.^{62,70,183,216} The actin polymerization reaction helps to form membrane extensions that push the virus into contact with the neighboring cell, thus generating an efficient mechanism for local dissemination in infected tissues.

Structures termed infectious or virological synapses were first described for the transmission of the human T-cell leukemia virus type 1 (HTLV-1).⁸³ These are areas of intimate contact between infected and uninfected cells reminiscent of immunological synapses. They provide a domain where virus assembly and release are focused with efficient targeting of the virus particles to the next host cell without access of antibodies from the outside.¹²⁹ Similar means of transfer have been described for herpesviruses and for the T-cell to T-cell transfer of HIV. Dendritic cells that bind HIV-1 via DC-SIGN help to transport the virus to lymph nodes where they present the virus to T cells, providing an efficient system for targeted infection of host cells through virological synapses.^{66,93}

PERSPECTIVES

The entry and uncoating mechanisms and strategies are highly variable depending on the virus and the target cell. They have in common that the viruses depend critically on the host cell and its activities. To extract the necessary assistance from the cell, viruses make use of the detailed *insider information* they have about the host organisms, their tissues, the cells, and a variety of molecular processes. This information has been acquired during millions of years of coevolution. Thus, although exceptionally simple in structure and composition, viruses are able to elicit exceedingly complex cellular responses. The induction of signals, the activation of endocytic pathways, the exploitation of intracellular targeting systems and molecular motors, and the cell-assisted mechanisms of uncoating provide examples of the ways in which viruses make use of cellular machinery during entry. As details unfold, interesting and important insights about the viruses and their hosts continue to emerge.

The entry program involves the transport of the incoming viruses and capsids through the membranes and the compartments of the cell, the stepwise dismantling of the virus particle, and the release of the genome. Entry and uncoating involve *switches* in particle structure and properties that have to occur in the right place at the right time. It is remarkable how little seems to be left to chance. In the future, these switches need more attention because they provide powerful targets for therapeutic and prophylactic intervention. Also, the cellular defenses against virus entry, ranging from degradation of incoming viruses to interferon-induced expression of interception proteins in the cytosol, deserve thorough study. After all, it is clear that, of the incoming cell-associated viruses, only a small fraction generally reach the intended goal.

It will be important to focus on the cellular factors involved in infection (i.e., on the Trojans and not only on the Trojan horses). They represent new targets for antiviral strategies. How viruses enter tissues and cells in intact organisms remains for the most part territory uncharted. New technologies and model systems are emerging that allow work at the whole animal level. A multidisciplinary approach that combines cell and molecular biology, structural biology, biochemistry, physiology, systems biology, and medicine as central disciplines is required. As important as knowing the pathogens, it will also be important in the spirit of an ancient greek aphorism to know ourselves (i.e., to understand the cell and molecular biology of the host cells).

Summary and Perspectives

Acknowledgment

exploit the biology of their hosts. Despite their comparatively limited genetic repertoire, viruses encode the information necessary to rewire their hosts to become viral factories. The intimacy of this relationship and the co-evolution of virus and host continue to provide unique mechanistic insights into host biology at the molecular, cellular, organismal, and population levels. Understanding this interplay enriches our understanding of the biosphere in general and virus–host relationships in particular, but also creates opportunities for the rational development of antiviral drugs, and for domesticating viruses as expression vectors, live-attenuated vaccines, and pesticides. This chapter provides an overview of the replication strategies of the major virus families that infect vertebrates, attempting where possible to emphasize the general principles that guide and constrain virus replication and evolution.

Viral Genome Diversity and Replication Strategies

Perhaps the most striking aspect of viruses at the molecular level is the diversity of their genome structures and replication strategies. Unlike cellular genomes, which consist uniformly of double-stranded DNA (dsDNA), viral genomes provide examples of almost every structural variation imaginable. As shown in Table 5.1, different families of viruses have genomes made of either double-stranded (ds) or single-stranded (ss) DNA or RNA; of either positive, negative, or ambisense polarity; of either linear or circular topology; and comprising either single or multiple segments. Each variation has consequences for the pathways of genome replication, viral gene expression, and virion assembly. This diversity argues strongly that viruses had several different evolutionary origins and can be thought of in D. J. McGeoch's evocative phrase as “mistletoe on the tree of life.” Accordingly, viral taxonomy above the family level is patchy, with only 22 of 87 families assigned to the six orders that are currently recognized.⁵⁷ However, it is likely that more distant phylogenetic relationships will emerge as the number of genome sequences and protein structures increase, and as more powerful comparison algorithms become available.

INTRODUCTION

Replication of genetic information is the single most distinctive characteristic of living organisms, and nowhere in the biosphere is replication accomplished with greater economy and apparent simplicity than among viruses. To achieve the expression, replication, and spread of their genes, different virus families have evolved diverse genetic strategies and replicative cycles to

Unique Biology of Virus Replication

As obligate intracellular parasites, all viruses depend heavily on functions provided by their host cells. This dependence, as well as the extensive metabolic overlap between host and parasite, limits the number of possible targets for antiviral therapy. Nevertheless, almost all viruses encode and express unique proteins, including enzymes, and many viruses exploit pathways of information transfer that are unknown elsewhere in the biosphere. This is particularly evident among the RNA

^bTopology of the encapsidated genome—note that some circularize during replication.

viruses, which are the only organisms that are known to store their genetic information in the form of RNA. They accomplish this by replicating their genomes via one of two unique biochemical pathways—either by RNA-dependent RNA synthesis (RNA replication), or, among the retroviruses, by RNA-dependent DNA synthesis (reverse transcription) followed by DNA replication and transcription. Both pathways require enzymatic activities that are not usually found in uninfected host cells and must therefore be encoded by the viral genome and expressed during infection. Furthermore, in some families of RNA-containing viruses those unique synthetic processes are required right at the start of the infectious cycle. This necessitates co-packaging of the corresponding polymerase and other associated enzymes with the viral genome during the assembly of viral particles in preparation for the next round of infection.

Whatever the structure and replication strategy of their genomes, all viruses must express their genes as functional messenger RNAs (mRNAs) early in infection in order to direct the cellular translational machinery to make viral proteins. The various genomic strategies employed by viruses can therefore be organized around a simple conceptual framework centered on viral mRNA (Figs. 5.1 and 5.2). By convention, mRNA is defined as positive-sense and its complement as negative-sense. The pathways leading from genome to message vary widely among the different virus families and form the basis of viral taxonomy. Although it is generally believed that viruses originated from cellular organisms, perhaps fairly recently in evolutionary times, it remains possible that some RNA viruses are descended directly from a primordial “RNA world” or “ribonucleoprotein world,” which may have predated the emergence of DNA and cells.

FIGURE 5.1. Pathways of primary mRNA synthesis by DNA viruses of animals. Hepadnaviruses replicate via reverse transcription of an ssRNA intermediate.

Subcellular Sites of Viral Replication

Most DNA viruses of eukaryotes transcribe and replicate their genomes and assemble progeny in the nucleus, the site of cellular DNA transcription and replication. The exceptions are the poxviruses, iridoviruses, and African swine fever virus, which replicate their DNA genomes partly or completely in the cytoplasm. In contrast, most RNA viruses replicate their genomes in the cytoplasm. However, in addition to the retroviruses that integrate DNA copies of their genomes into the host chromosomes, other notable excep-

tions to this generalization are the orthomyxoviruses, bornaviruses, and many plant-infecting rhabdoviruses, whose linear negative-sense RNA genomes replicate in the nucleus. The circular RNA genome of hepatitis delta virus (HDV), also replicates in the nucleus (Table 5.1). Each site of replication presents distinct opportunities and challenges in terms of which cellular components and pathways are available to be co-opted, and how the synthesis and trafficking of viral proteins, genome replication, virion assembly, and the release of progeny can be coordinated. For example, RNA splicing occurs only in the nucleus, so among the RNA viruses,

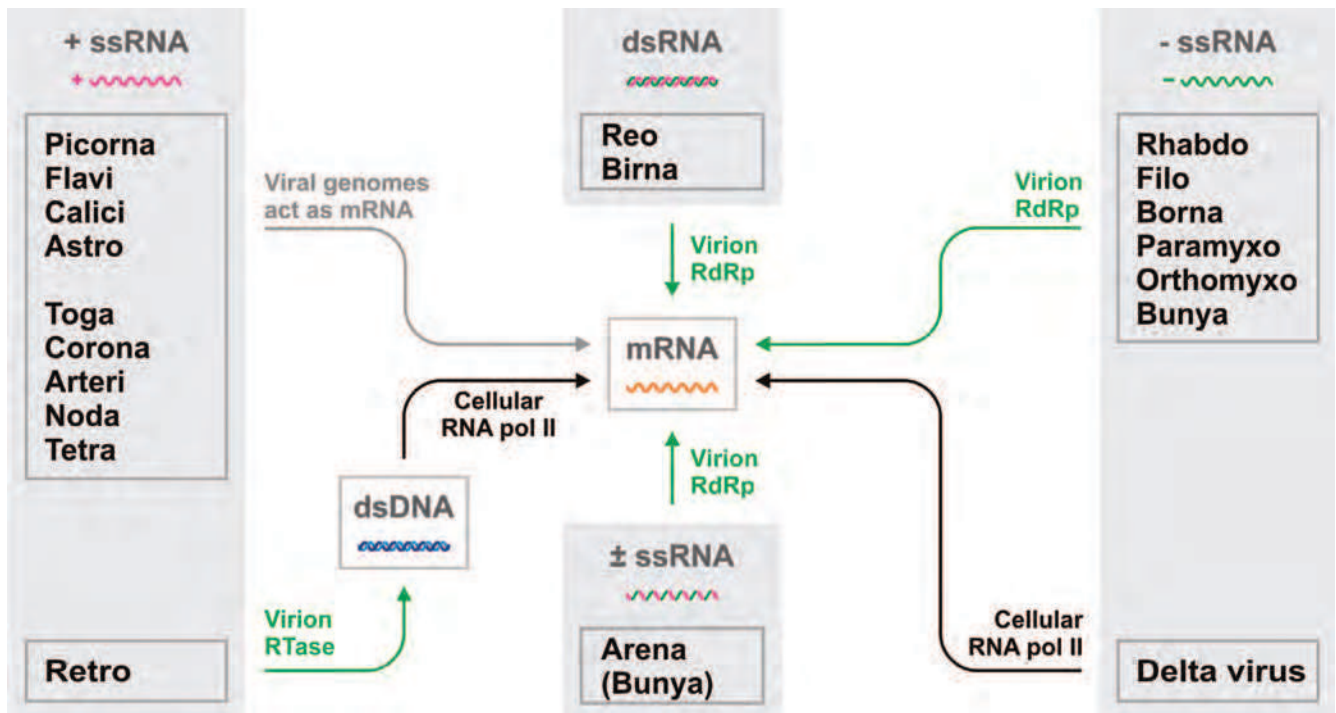

FIGURE 5.2. Pathways of primary mRNA synthesis by RNA viruses of animals. How RNA viruses produce mRNA at the start of infection depends upon the nature of the viral genome.

this mechanism of accessing more than one open-reading frame in a single transcript can be employed by only the retro-, orthomyxo-, and bornaviruses that transcribe there. It is remarkable that the paramyxoviruses that replicate in the cytoplasm have evolved a transcriptional editing mechanism that achieves a similar result.⁹⁹ Irrespective of the site of replication (nuclear or cytoplasmic) the viral replication machinery itself is frequently compartmentalized within specific structures or viral-induced organelles. For example, herpesviruses form replication compartments within the nucleus at nuclear speckles,^{16,88} and many RNA viruses that replicate in the cytoplasm do so in association with membranes or an inclusion-like structure that contains the viral replication machinery.²⁵

Evasion of Host Response to Infection

To ensure their survival, host organisms have evolved a variety of responses to combat viral infection. In turn, many viruses express specific gene products that act to circumvent one or more of those antiviral defense mechanisms. Examination of these measures and countermeasures provides a revealing glimpse into the heart of the host–parasite relationship as it plays out in nature. Host-defense mechanisms can be categorized as innate or adaptive. Among the former, which operate at the cellular level, are apoptosis (programmed cell suicide that limits the spread of infection, see Chapter 8), the induction and action of interferons in vertebrates (inducible cytokines that render cells resistant to infection by inducing a multifaceted antiviral state, see Chapter 8), and RNA interference in plants and invertebrates (a sequence-specific mechanism of RNA degradation, see Chapter 8). Adaptive immune mechanisms operate at the organismal level, and include the cell- and antibody-mediated immune response (see Chapter 9). Increasingly, specific restriction factors have been identified that limit the replication of subsets of viruses. Such factors include tripartite motif containing protein 5 (TRIM5), which appears to trigger the premature disassembly of the incoming human immunodeficiency virus type 1 (HIV-1) capsid to limit the establishment of infection; the apolipoprotein B mRNA editing, enzyme catalytic (APOBEC) family, which induces a biased hypermutation in RNA through its cytidine deaminase activity that converts C to U; and bone marrow stromal antigen 2 (BST2)/Tetherin, which is incorporated into the membranes of some enveloped viruses resulting in a linking together of budding viral particles. Although a number of other cellular proteins have been termed “restriction factors,” they are distinguished by their dependence on induction by interferon and are therefore not considered here. In different viruses, mechanisms and gene products have been identified that inhibit apoptosis, intercept interferons or suppress their activities, obstruct RNA interference, either evade or suppress different arms of the adaptive immune response, or block intrinsic restriction factors.^{4,36,46,47,63,70,90,92,93,100}

Viruses are sensed by the host in ways that appear to involve recognition of unique signatures present in viral genomes or gene products. Such signatures are termed pathogen-associated molecular patterns (or PAMPS), and are recognized by an array of host pathogen-recognition receptors (or PRRs). Those PRRs include the toll-like receptors (TLRs), which are membrane-associated molecules that sense invading pathogens directly at the plasma membrane or during endosomal transit. The retinoic acid inducible gene (RIG)-

like receptors (RLRs), which are cytoplasmic RNA helicases that recognize the products of RNA viral nucleic-acid replication, and the absent in melanoma 2-like receptors that recognize cytoplasmic DNA. Although viral ligands have not been defined, the NOD-like receptors (NLRs), which sense bacterial peptidoglycan, appear to also detect some viruses. A striking example of such PRR function is the detection of off-pathway products of replication such as abortive initiation products, dsRNA, and defective viral genomes, which can serve as ligands for the cytoplasmic sensors RIG-I and melanoma differentiation association protein 5 (MDA-5) to engage in a signaling cascade that leads to the activation of interferon.⁴⁰ The net result of interferon activation is both the blocking of infection within the cell, and the preactivation of defense mechanisms in neighboring cells to render them less susceptible to infection. The latter is accomplished by the transcription of interferon (IFN)–stimulated genes (ISG), which themselves act to block various steps in the replication cycle of DNA and RNA viruses⁹³ (see Chapter 8). In turn, viruses themselves have evolved countermeasures to such host-defense mechanisms that act to block the induction of IFN itself, or to interfere with specific ISG function.^{22,43} The elaborate arms race between viruses and their hosts is described in more detail in Chapter 8 and Chapter 9, as well as within the specific chapters dealing with individual virus families. Molecular signatures of this arms race throughout evolution are also visible in the sequences of virus and host genes. Retroviruses provide a unique insight into this, since they integrate into the host genome. Evidence for integration of portions of other viral genomes into the host chromosome including RNA viruses such as bornavirus, and lymphocytic choriomeningitis virus, has also emerged.^{33,80}

Error Prone Nature of RNA Replication

The polymerases that catalyze RNA replication and reverse transcription have minimal proofreading activities. The polymerase error rate of such RNA-dependent RNA polymerases (RdRp's) and reverse transcriptases is approximately three orders of magnitude higher than that of DNA-dependent DNA polymerases, and approaches the reciprocal of their genome length.^{28,52,74} The net result is that the genomes of RNA viruses evolve at a much faster rate than those of their hosts. Biologically, RNA viruses therefore represent a swarm of sequences around a consensus sequence or master sequence.^{31,62} This molecular swarm provides a fertile source of phenotypic variants that can respond rapidly to changing selection pressures by shifting its composition. As a consequence, RNA viruses can evolve up to 1 million times faster than DNA-based organisms. The error prone nature of RNA virus replication is also critical for pathogenesis in infected hosts. The diversity of viral sequences regenerated following bottleneck transmission of HIV in humans,⁸⁹ and experimental poliovirus infection of mice,^{84,101} provide striking examples of this *in vivo*. In the case of HIV, the resulting sequence variation achieved following transmission of a limited number of genomes is enormous and accounts for—among other phenotypes—the rapid escape of the virus from neutralizing antibody, and the escape from antiviral monotherapy.

Such rapid rates of evolution are not without cost for the RNA viruses, however, because higher polymerase error rates impose upper limits on genome size. The combination

of replicative error rate and genome size defines an “error threshold” above which a virus cannot maintain even the sequence integrity of its quasispecies.³¹ As a result, few RNA virus genomes contain more than 30 kilobases (kb) and most have between 5 and 15 kb. RNA genomes of this size are poised just below their error thresholds, and although their genetic diversity inevitably wastes individual progeny that carry deleterious mutations, the cost is offset by the potential for rapid evolutionary response to changing selective pressures. This positioning of RNA viruses—just below their error threshold—may also present an opportunity for antiviral development. Specifically, therapeutics that lead to an increase in error rate can shift the balance beyond the error threshold toward “error catastrophe.” Indeed evidence has accumulated that this is one such mechanism by which ribavirin, an adenosine analog, may inhibit the replication of some RNA viruses.²¹ The largest RNA virus genomes currently recognized are those of the coronaviruses, which approach a size of 30 kb. Strikingly, it appears that for coronaviruses the non-structural protein nsp14 functions as an RNA exonuclease that may function as a proofreading mechanism that could help maintain genome integrity.²⁷

Levels of Segmentation

Another distinctive feature of eukaryotic cells—besides their partitioning into nuclear and cytoplasmic compartments—has a profound influence on the biology of their viruses. On most mRNAs, eukaryotic ribosomes require a methylated mRNA cap structure at the 5′ end that plays a critical role in signaling the initiation of protein synthesis. As a result, eukaryotes typically conform to the “one mRNA one polypeptide chain” rule; with very few exceptions, each message operates as a single translational unit. Similarly, viral RdRp’s generally appear somewhat restricted in their ability to access internal promoter elements on RNA templates, and this creates a problem of how an RNA virus can derive several separate protein products from a single genome.

Through evolution, different RNA virus families have found three different solutions: fragmentation at the level of proteins, mRNAs, or genes, with some viruses using more than one of those solutions. For example, RNA viruses in the picorna- toga-, flavi-, and retrovirus families rely on extensive proteolytic processing of polyprotein precursors to derive their final protein products.²⁹ Others (in the orders *Mono-negavirales* and *Nidovirales*) depend on complex transcriptional mechanisms to produce several monocistronic mRNAs from a single RNA template.^{1,91} Still others (in the reo-, orthomyxo-, bunya-, and arenavirus families, among others) have solved the problem by fragmenting their genomes and assembling virions that contain multiple genome segments, each often representing a single gene.^{34,69,76} Among plant viruses, such RNA genome segments are often packaged into separate virions, necessitating co-infection by several virus particles to transmit infectivity,¹⁰⁷ but the genome segments of animal viruses are typically co-packaged into single virions. In contrast, DNA viruses seldom use either genome segmentation or polyprotein processing. This is likely due to the relative ease with which monocistronic mRNAs can be transcribed from internal promoter elements of dsDNA, and the extensive use of differential splicing of nuclear transcripts to express promoter-distal open-reading frames.

Host Cell Components for Replication

Viruses depend on their host cells to support their replication, and this degree of dependency—to some extent—reflects their genome size. Although all viruses depend on the host translational machinery, large DNA viruses, such as mimivirus, may encode specific initiation factors that may provide a translational advantage for viral genes.¹⁸ Entry of viruses into cells usually requires specific host-cell factors, and can require co-opting of cellular endocytic pathways.⁷¹ The end point of entry is the release of the minimal viral replication machinery into the host-cell cytoplasm to initiate infection. How viruses establish infection in the hostile environment of the host cell remains one of the least understood steps of the viral replication cycle. The input genomes must either associate directly with ribosomes in the case of positive-strand RNA viruses, or be copied into mRNA, in the case of the negative-strand RNA viruses, dsRNA viruses, and DNA viruses. Because the particle-to-infectivity ratio of some viruses approaches 1:1, this process must be highly efficient despite its inherent challenges. Our knowledge of the subsequent viral rewiring of host-cell structures to establish replication compartments, traffic viral proteins and nucleic acids, and assemble viral particles is also far from complete, but has yielded a wealth of information into host biology as well as that of the viruses themselves. Indeed, study of viruses has contributed enormously to our understanding of promoters, transcriptional enhancers, the mRNA cap structure, RNA splicing, and mechanism of translation. Similarly, critical discoveries in host-cell transport and trafficking pathways including endocytosis, exocytosis, and secretory transport were achieved because of the ability to synchronize infections with viruses. Although systematic approaches including RNA interference (RNAi), proteomics, gene-knockout studies, and microarrays are helping to further transform our understanding of the virus–host interaction at the molecular level, we have yet to understand fully the complexities of the interactions of any virus with its host. Zoonotic viruses must strike a balance for optimal replication in often quite disparate hosts, likely adding further complexity to this intimate relationship. Striking examples of this are provided by members of the *Flaviviridae*, such as Dengue virus (which replicates in both its mosquito host and animals), and experimentally with many viruses including vesicular stomatitis virus (which replicates in virtually all eukaryotic cells in culture).

STRUCTURES AND ORGANIZATION OF VIRAL GENOMES

DNA versus RNA Genomes

Among families of viruses that infect vertebrates, those with RNA genomes outnumber those with DNA genomes by about 2 to 1 (Table 5.1); among viruses infecting plants the disparity is even greater. Indeed, no dsDNA viruses of plants are known except for those that like the hepadnaviruses of vertebrates, replicate via reverse transcription (see Chapter 68). This remarkable observation remains to be explained, but it may suggest that non-RT dsDNA viruses arose only after animals and plants diverged. Be that as it may, the prevalence of RNA viruses attests to the evolutionary success and versatility of RNA as genetic material for smaller genomes. As discussed

previously, the high error rates of RNA replication restrict RNA genome sizes to 30 kb or less, whereas proofreading and error repair ensure sufficiently accurate replication of DNA virus genomes as large as that of the 1200-kb megaviruses.³ In addition, the fact that DNA is more chemically stable than RNA likely explains why all known viruses of thermophilic hosts have dsDNA genomes.⁵⁷

Single- and Double-Stranded Genomes

Although all viral genomes replicate via conventional Watson-Crick base pairing between complementary template and daughter strands, viruses that belong to different families encapsidate and transmit different molecular stages of the genome replication cycle. Families of ssRNA viruses outnumber families of dsRNA viruses by almost 10 to 1, roughly the inverse of the ratio between ssDNA and dsDNA viruses. In view of the greater chemical stability of double-stranded nucleic acids of both types, this difference calls for an explanation. Two possibilities seem plausible: First, dsRNA viruses must somehow circumvent the translational suppression that can result from the coexistence of equimolar amounts of the sense and antisense RNAs. How the dsRNA reoviruses solve this problem is addressed in Chapter 44. Second, dsRNA is widely recognized by the cells of higher eukaryotes as a signal for the induction of defense mechanisms that act to suppress viral replication, such as the IFN system in vertebrates (see also Chapter 8), gene silencing in plants, and RNAi in a variety of organisms.^{15,40,93,106} These effects probably suffice to explain the relative scarcity of dsRNA virus families.

For these same reasons, it is important even for ssRNA viruses to limit the accumulation of replicative intermediates that contain regions of dsRNA, and the strategies to ensure this differs between the positive- and negative-sense RNA viruses. All known positive-strand RNA viruses synthesize disproportionately low amounts of the negative-strand RNA—typically 1% to 5% of the levels of the positive-strand—and thereby minimize the potential for dsRNA accumulation. Moreover, because the replication of these viruses appears to universally occur in sequestered membranous compartments, there appears to be a physical separation of the replicative intermediates from the host-cell cytoplasm, likely reducing the chances of detection.²⁵ In contrast, negative-strand RNA viruses, which need substantial amounts of both positive- and negative-sense RNAs to use as messages and progeny genomes, respectively, prevent the complementary RNAs from annealing to one another by encasing the genomic and antigenomic RNAs with a viral nucleocapsid protein.^{2,44} Here, RNA synthesis also appears confined at some stages of infection to specific subcellular compartments that may help serve to limit detection of viral products of RNA synthesis by the innate immune system.

Positive, Negative, and Ambisense Genomes

The differences between positive- and negative-strand RNA viruses extend beyond the polarity of the RNA assembled into virions. Positive-sense RNA genomes exchange their virion proteins for ribosomes and cellular RNA binding proteins at the onset of infection. Once synthesized and assembled the virus-specified RdRp and other nonstructural proteins replace the ribosomes to accomplish RNA replication. Virion structural proteins are reacquired during the assembly of progeny

virions. In contrast, negative-strand RNA genomes and their antigenomic complements remain associated with their nucleocapsid proteins, both within the viral particles and throughout the viral replication cycle, even during RNA replication. These fundamentally different adaptations can be attributed to the fact that whereas positive-sense RNA genomes must satisfy criteria for translation that are dictated by the host cell, negative-sense RNA genomes must only satisfy the template requirements for the virus-specified RdRp because they are replicated but never translated. Although the precise mechanism by which the protein-coated templates of negative-strand RNA genomes are copied by their cognate polymerases is not fully understood, short naked RNAs that correspond to the terminal promoters can be copied by their viral polymerases.^{26,59,73} Such experimental evidence is consistent with a model for RNA synthesis in which the nucleocapsid protein is transiently displaced from the template RNA during copying of the genome.

The dsRNA virus genomes are intermediates between the two. The parental genome remains sequestered within a subviral particle during the synthesis of the unencapsidated positive-sense mRNA transcripts, which are replicated to produce progeny dsRNAs only after being assembled into subviral core particles.⁸¹ Although the core RdRp's of each of these viruses are structurally as well as functionally analogous, the distinctions in the genomic structure likely place additional structural constraints on the viral polymerase complexes.

Linear and Circular Genomes

Genome replication not only requires an acceptable error rate as described previously, but must also avoid the systematic deletion or addition of nucleotides. Genome termini are particularly troublesome in this respect, a fact that has been dubbed “the end problem.” For DNA replication, the end problem is exacerbated by the fact that DNA polymerases cannot initiate the synthesis of daughter strands and must therefore use primers, thus creating additional complications of replicating the primer-binding site(s). Among several known solutions, the most economical and widespread in nature is to eliminate the ends altogether by covalently circularizing the genomic DNA, as occurs in the genomes of prokaryotes. Polyoma-, papilloma-, circo-, and anellovirus genomes follow this model, and the dsDNA genomes of herpes and hepadnaviruses, although linear, in virions are covalently circularized before replication. Poxviruses and asfiviruses also have linear dsDNA genomes, but in these cases the individual complementary strands are covalently continuous at the termini of the duplex, which provides another solution to the end problem. A similar close-ended duplex DNA is generated during the replication of the ssDNA genomes of parvoviruses (Chapter 57). Terminal redundancy (iridoviruses), inverted terminal repeats (adenoviruses), and the use of protein primers that do not occlude the binding site (adenoviruses and hepadnaviruses) represent the other ways that DNA viruses have evolved to ensure accurate and complete replication of their genome termini.

Unlike DNA polymerases, most RNA polymerases do not require primers, so RNA genomes are less susceptible to the end problem. Accordingly, most RNA genomes are linear molecules. Covalently closed circular RNAs are found only in HDV in animals (Table 5.1) as well as among the viroids and other subviral RNA pathogens that infect plants. Nevertheless the termini of linear RNA genomes are vulnerable to degra-

dation, and their replication is likely to be particularly error prone. Consequently, every family of RNA viruses has features designed to preserve the termini of the genome.⁶ For example, many positive-strand RNA viruses have a 5' cap structure and 3' polyadenylate tail that serve to protect eukaryotic RNAs against degradation, and a similar role is likely played by the VPg that is covalently linked to the 5' end of the picornavirus genomes,⁶⁴ and by the stable RNA secondary structures present at the 3' end of the flaviviral RNA and other genomes. The 3' ends of many plant virus RNAs form clover leaf structures that resemble transfer RNAs (tRNAs) so closely that they are recognized by the cellular tRNA charging and modifying enzymes.³⁰ In addition to playing protective roles, terminal modifications of positive-sense RNAs may also serve to bring their ends together by binding to interacting cellular proteins such as the poly(A) binding protein and cap-binding complex, thereby forming noncovalent functionally circular complexes that may promote repetitive translation by ribosomes and repetitive replication by RdRp's.^{49,102}

Unlike the genomes of positive-sense RNA viruses, negative-sense and ambisense RNA virus genomes rarely carry covalent terminal modifications. Those RNA genomes show some degree of terminal sequence complementarity that is thought to lead to the formation of a panhandle type of structure that, in the case of the segmented viruses, favors RNA replication. Because the templates are encapsidated by the viral nucleocapsid protein, it is not clear how the RNA bases can engage in base-pairing interactions between the termini. However, complementarity between the genomic termini favors replication and likely promotes polymerase transfer during RNA synthesis to ensure efficient reinitiation of replication. In other solutions to the end problem among the RNA viruses, retroviral genomes are terminally redundant and have direct repeats of 12 to 235 nucleotides at each end that maintain and restore the integrity of the termini during reverse transcription and virus replication (see Chapter 47).

Segmented and Nonsegmented Genomes

As discussed previously, segmentation of RNA genomes is one way to facilitate the production of multiple gene products in eukaryotic cells, but it also means that the various segments must each contain appropriate *cis*-acting signals to mediate their expression, replication, and assembly into virions. In some virus families whose members have segmented genomes (e.g., the orthomyxoviruses and some reoviruses), these signals comprise conserved sequences at the RNA termini, but in others (e.g., the bipartite nodaviruses and tetraviruses) sequence conservation between the segments is minimal. In these latter cases, the specificity of RNA replication and assembly is presumably dictated by conserved RNA secondary or tertiary structures. Moreover, segmentation of the viral genome requires a level of coordination to ensure that the correct amounts of viral gene products are expressed and to ensure the packaging of multiple genome segments to form infectious virus particles. How such coordination is achieved is not understood. Furthermore, in the case of the negative-sense, ambisense, and dsRNA viruses that have segmented genomes, a mechanism is required to ensure that the polymerase is packaged into the virus particle so that the incoming segments can be transcribed into mRNA. For the dsRNA viruses the polymerase is an integral structural component of the core

transcribing particle ensuring that the polymerase and capping machinery are present within the incoming particle. In the case of the arenavirus, Machupo, this is a function of a small viral protein Z, which locks the polymerase on the promoter in an inactive form.⁶⁰

Evidently, the evolutionary barrier between viruses with segmented and nonsegmented RNA genomes is readily transversed because both genome types occur in members of the alphaviruslike supergroup, a taxonomic cluster based on phylogenetic comparisons of nonstructural protein sequences. Indeed, among the tetraviruses, segmented and nonsegmented genomes can even be found in the same family. Furthermore, the genomes of some togaviruses, rhabdoviruses, and paramyxoviruses, which are naturally nonsegmented, have been experimentally divided into segmented genomes without destroying viral infectivity,^{38,96} thus confirming the flexibility of RNA genomes in this regard. Nevertheless, genome segmentation has major effects on the biology of a virus because individual segments can reassort between dissimilar strains in co-infected cells, which enables segmented genome viruses to make substantial evolutionary leaps by horizontal gene transfer. This mechanism underlies the antigenic shifts that produce new pandemic strains of the orthomyxovirus influenza virus (see Chapter 40 and Chapter 41).

As discussed previously, genome segmentation is almost unknown among DNA viruses, most likely because internal initiation of transcription and alternative splicing provide more facile ways to access multiple open-reading frames. Only the polydnviruses, a family of dsDNA viruses that infect parasitic wasps and participate in a complex and unusual host–parasite relationship, show extensive DNA segmentation.⁷

Cis-Acting RNA Signals and Specificity

Replication and packaging of viral RNAs display striking specificity; both processes unerringly pick the correct viral molecules from among thousands of cellular RNAs that may be much more abundant. This is generally attributed to the presence of *cis*-acting signals that selectively channel the viral RNAs into replication and assembly complexes, but in most RNA virus genomes these signals remain to be clearly identified. Those that have been characterized most, comprise not linear nucleotide stretches, but RNA secondary structures such as bulged stem-loops, tRNA-like cloverleaves, and pseudoknots, which are believed to create distinctive three-dimensional molecular shapes that interact specifically with the viral enzymes and structural proteins. Although high-resolution structures have been determined for some RdRp's, reverse transcriptases, and several viral capsids, our understanding of the molecular basis of specificity in RNA replication and virus assembly is limited by the scant knowledge of the three-dimensional structures of viral RNA and its *cis*-acting signals. However, the structural basis of RNA specificity during replication and assembly has often proved elusive, perhaps because the specificity determinants can be redundant, dispersed, or global properties of the viral genome. Furthermore, in both RNA replication and assembly, specific interaction is followed by less-specific RNA–protein interactions that propagate the reactions. The transitions between these different stages are largely unexplored, and much remains to be learned concerning the recognition of *cis*-acting RNA signals and how they promulgate RNA replication and assembly. In the case of some viruses, the products of

replication are selectively channeled into the assembly pathway, thereby diminishing the need for separate assembly signals.

Promising advances in our understanding of *cis*-acting regions of RNA viral genomes have recently come from the application of a chemical probing methodology termed selective 2' hydroxyl acetylation analyzed by primer extension (SHAPE), first applied to provide an overview of the complete genome of HIV-1.¹⁰³ In addition to correctly identifying known structures within the HIV-1 genome, several structures were identified within the coding regions at regions close to the positions of polyprotein processing. Such structured elements are thought to lead to a slowing of ribosomes to facilitate the correct folding of the preceding region of the polypeptide chain, although data proving this are lacking. Whatever the function of such structured elements, application of this methodology promises to improve our definition of the *cis*-acting elements within RNA virus genomes as well as the overall structure of viral genomes.

Satellite, Dependent, and Defective Genomes

Occasionally, subviral genomes arise that are neither independently infectious nor essential for infectivity, but nevertheless contain *cis*-acting signals that promote their own replication and/or packaging by the proteins encoded by another virus. Such satellite nucleic acids are parasitic on the parental virus and can modulate its replication and virulence.⁹⁴ Most commonly, they are ssRNAs, but dsRNA and ssDNA satellites are also known. Among the RNA viruses of animals, a prime example is hepatitis delta virus (or HDV), which packages its ssRNA genome in virion proteins encoded by the hepadnavirus hepatitis B virus and can severely exacerbate its pathogenicity.⁹⁷ Dependence of an RNA satellite on a DNA virus parent is unusual; more commonly satellite RNAs are replicated and encapsidated by the proteins of an RNA virus parent with which they share at least some sequence homology. In some instances, satellite RNAs encode their own distinct capsid proteins, or proteins required for RNA replication (as in the case of HDV), but in others they are translationally silent. Satellite RNAs are much more common among the viruses of plants than those of animals (see Chapter 72), perhaps because the transmission of animal viruses between hosts generally involves narrower bottlenecks that select against the spread of satellites. Dependence of one virus on another is also found occasionally among viruses with DNA genomes. For example, adenovirus-associated virus (family *Parvoviridae*, genus *Dependovirus*) requires coinfection of host cells by adenoviruses or herpesvirus to provide helper functions necessary for its replication.

In contrast to the transmission of viral infection between hosts, the spread of infection within a single animal usually involves successive episodes of localized viral replication that resemble the conditions of plaque formation and serial high multiplicity passage in cell culture. These conditions favor the generation and amplification of defective viral genomes, which can arise from a simple internal deletion of genes as well as more complex genome rearrangements that occur during RNA replication. Like satellite RNAs, defective RNAs parasitize the parent virus and usually interfere with its replication, but because they also depend upon it for their own survival, they typically establish a fluctuating coexistence. Most families of animal RNA viruses readily generate defective interfering (DI) RNAs in cell culture, but their influence on viral disease and evolution is less well understood.

EXPRESSION AND REPLICATION OF DNA VIRUS GENOMES

DNA Virus Genome Strategies

Viral DNA genomes range in size from the 1.8-kb circoviruses to the 1,200-kb genomes of the *Megaviridae*.³ This difference in the coding capacity means that viruses from different families vary widely in how many of the functions necessary for viral replication they can encode themselves. For example, DNA viruses with small genomes such as the polyoma-, papilloma-, and parvoviruses use host-cell enzymes for transcription and replication (Figs. 5.3 and 5.4). Those with intermediate-size genomes (up to 35 kb) such as adenoviruses, encode much of their DNA replication machinery including a DNA polymerase, terminal protein and ssDNA binding protein, but they employ cellular RNA polymerase II and III for transcription (Fig. 5.5). Those with larger genomes (150 to 350 kb), such as the herpesviruses and poxviruses, encode DNA polymerases and binding proteins. In the case of herpesviruses, multiple specific transcription factors serially modify the promoter specificity of RNA polymerase II (Fig. 5.6), or in the case of the poxviruses multi-subunit transcriptase complexes perform all the functions of capping and polyadenylation as well as RNA transcription (Fig. 5.7). Hepadnaviruses buck this general trend in that they are small genomes (3 kb) but encode the DNA polymerase/reverse transcriptase that executes their unique mechanism of DNA replication via an ssRNA intermediate (Fig. 5.8).

Because cellular DNA synthesis occurs during the S phase of the cell cycle and not at all in terminally differentiated G0 cells, viruses that depend on the host DNA polymerase must either wait for the infected cell to enter S phase spontaneously, as in the case of parvoviruses, or early in infection, they must express one or more viral oncogenes to override the regulation of the cell-cycle control proteins p53 or pRb and thereby stimulate infected cells to enter S phase, as in polyomaviruses and papillomaviruses. Inactivation of pRb releases cellular transcription factor E2F, which induces expression of the cellular DNA polymerase α primase, DNA polymerase δ , ssDNA binding protein, and several critical cellular enzymes that are involved in both the *de novo* and the salvage pathways of deoxynucleotide triphosphate (dNTP) biosynthesis, including ribonucleotide reductase, thymidylate synthetase, dihydrofolate reductase, deoxyuridine triphosphate nucleotidohydrolase (dUTPase), and thymidine and thymidylate kinases. Viruses with large DNA genomes (e.g., herpesviruses and poxviruses) encode some of those enzymes themselves and can thus replicate in nondividing cells and other environments that would not normally support DNA replication, such as terminally differentiated cells of the nervous system (some herpesviruses) or even the cytoplasm (poxviruses). Although these viral genes are often dispensable for virus replication in actively dividing cells in culture, they can exert a profound influence on viral virulence in infected organisms and thus provide targets for chemotherapeutic intervention. For example, the thymidine kinase gene of some herpesviruses (but not the host enzyme) phosphorylates the prodrug acyclovir to generate a dNTP analog that terminates nascent strands during DNA synthesis.³²

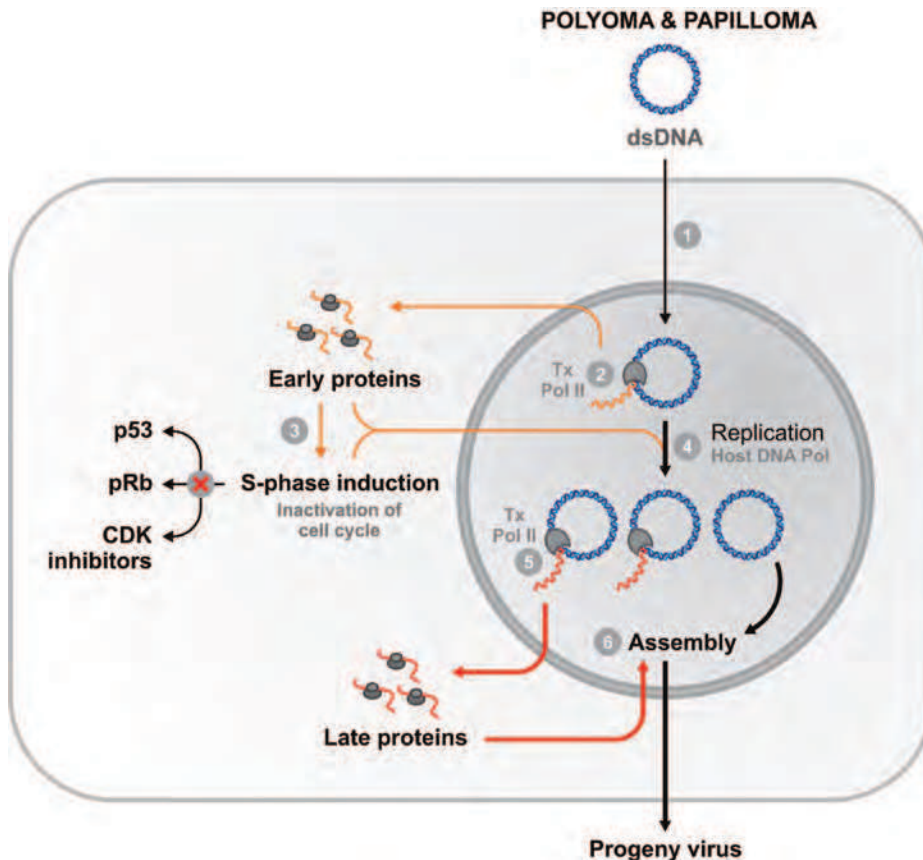

FIGURE 5.3. Simplified view of the replication scheme of *Polyomaviridae* and *Papillomaviridae*. The circular dsDNA genome is transported to the nucleus (step 1) where cellular RNA polymerase II transcribes the early genes (step 2) that encode the viral oncoproteins or transforming (T) antigens. The products of step 2 interfere with the host-cell cycle control proteins p53 and pRb or interact with inhibitors of cyclin-dependent kinases (CDKs) to stimulate cellular DNA replication (step 3). In nonpermissive cells that cannot support the vegetative replication cycles and therefore survive the infection, these early events can lead to neoplastic transformation. In permissive cells, the viral DNA is replicated by the host-cell DNA polymerase (step 4), following which cellular RNA pol II can transcribe the late genes that encode viral structural proteins (step 5). The assembly of viral particles occurs in the nucleus (step 6). The thickness and color intensity of the arrows signifies the predominant events.

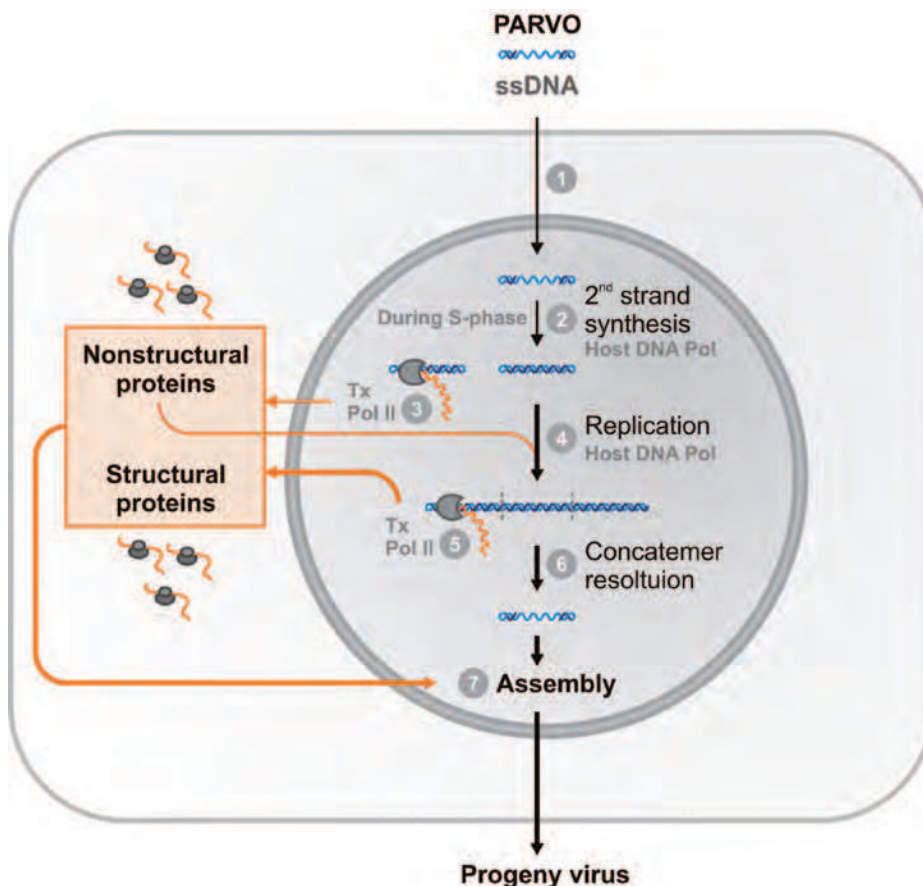

FIGURE 5.4. Simplified view of the replication scheme of *Parvoviridae*. Following entry, the linear ssDNA genome is delivered to the nucleus (step 1) where self-primed second strand synthesis is mediated by the host DNA polymerase during the S phase of the cell cycle (step 2). The resulting dsDNA hairpin is transcribed by the cellular RNA polymerase II (step 3) to produce mRNAs that encode viral nonstructural and structural proteins, and is ligated to form a covalently continuous duplex. The nonstructural proteins promote further DNA replication by the host DNA polymerase, which occurs via a rolling hairpin mechanism to produce double-stranded concatamers of the viral genome (step 4). The concatamers are templates for transcription by host RNA polymerase II to produce further viral proteins (step 5), and they are resolved (step 6) prior to assembly (step 7) into viral particles.

FIGURE 5.5. Simplified overview of the replication scheme of *Adenoviridae*.

The linear dsDNA genome is delivered into the nucleus (step 1), where it is transcribed by the host cell RNA polymerase II (step 2) to produce the early gene products including oncoproteins and the viral DNA polymerase. In adenoviruses of primates, the host RNA polymerase III also transcribes the genome to produce VA RNAs that act as interferon antagonists (step 3). The early gene products override cell cycle controls and inhibit apoptosis (step 4) as well as provide the essential viral polymerase components for genome replication (step 5). Following DNA replication, the late genes are transcribed by the host RNA polymerase II from a single major late promoter, and following extensive differential splicing provide the viral structural proteins (step 6). Virus assembly (step 7) occurs in the nucleus.

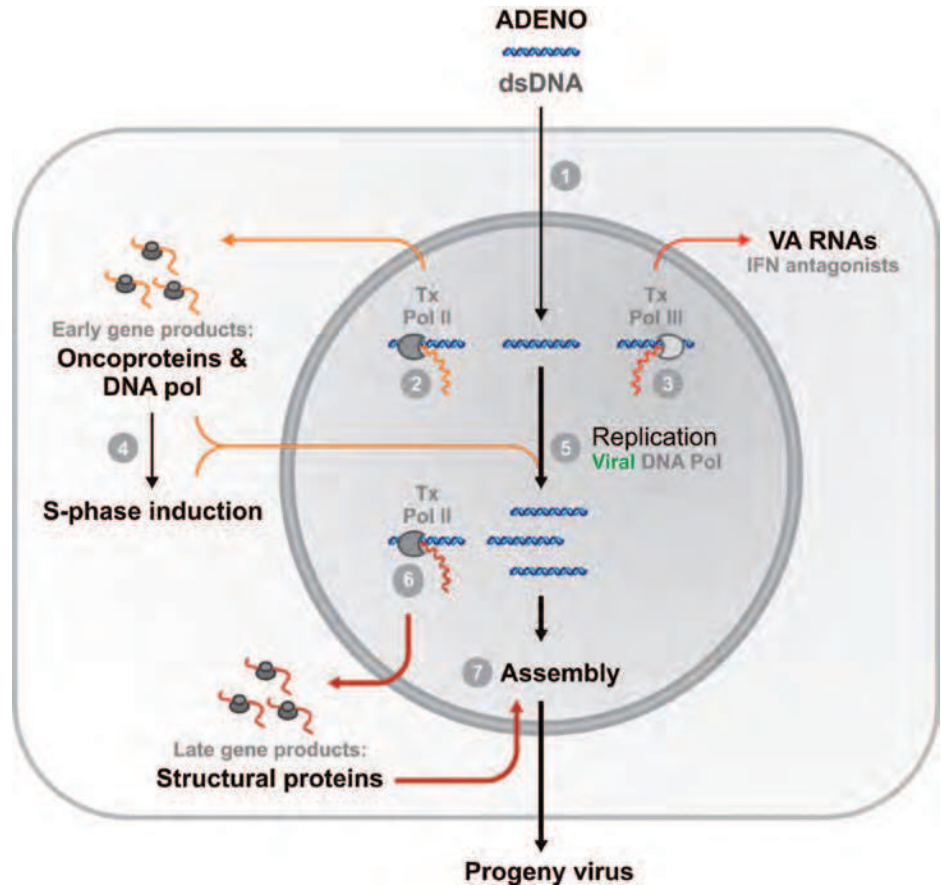

FIGURE 5.6. Simplified overview of the replication scheme of *Herpesviridae*.

The linear genomic dsDNA genome is delivered to the nucleus, where it undergoes covalent circularization (step 1). Cellular RNA polymerase II transcribes the immediate-early α genes (step 2) that encode transcription factors that mediate the host RNA polymerase II recognition of the promoters for the delayed-early β genes (step 3). Those genes encode the viral DNA polymerase and other proteins required for genome replication (step 4) as well as transcription factors required for the pol II-mediated expression of the late γ genes that encode most of the structural proteins (step 5). Virions assemble in the nucleus (step 6) and exit through the nuclear pore. The assembled virion contains the necessary transcription factors for expression of the immediate-early α genes on infection of the next cell. Note that this scheme represents only the vegetative cycle of *Herpesviridae* replication. Readers are referred to the individual *Herpesviridae* chapters regarding the establishment, maintenance of, and reactivation from latency.

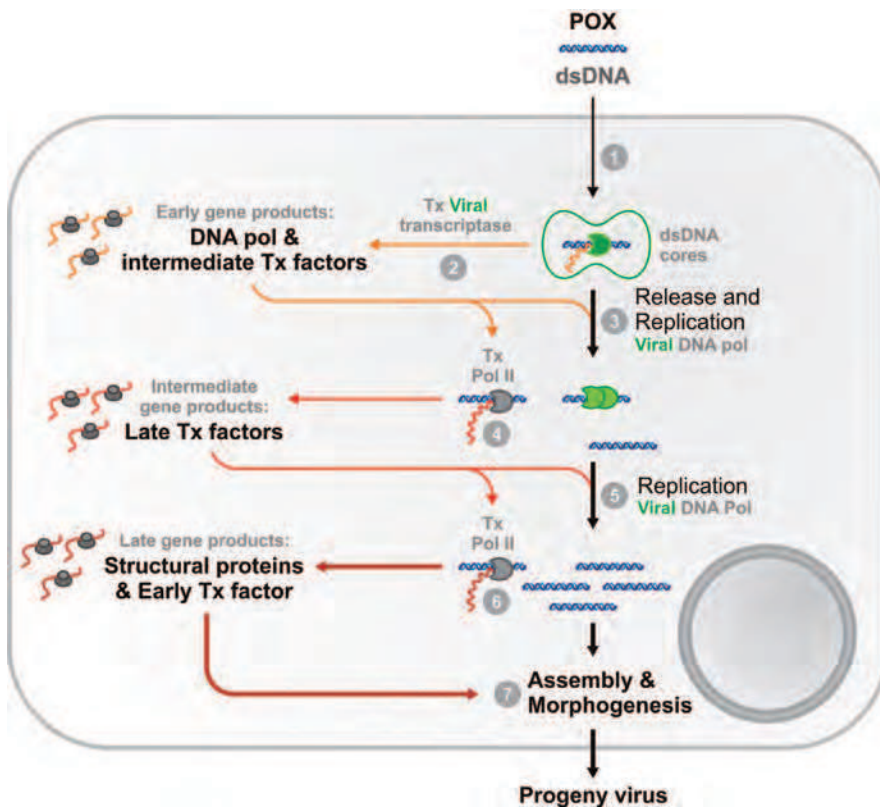

FIGURE 5.7. Simplified scheme of the replication of *Poxviridae*. Entry delivers the viral core containing the dsDNA genome into the cytoplasm—the site of viral RNA synthesis (step 1). In the cytoplasm the multisubunit virion DNA-dependent RNA polymerase transcribes the early viral genes (step 2), which comprise approximately 50% of the genome. The early gene products include factors that mediate the release of the dsDNA into the cytoplasm (second stage uncoating), the viral DNA polymerase and associated enzymes required for replication (step 3), and transcription factors that direct the viral RNA polymerase to transcribe a limited number of intermediate genes (step 4). DNA replication proceeds via a rolling hairpin mechanism (step 3 and 5) similar to that for parvoviruses, and is concurrent with the expression of the intermediate gene products (step 4). The intermediate gene products include transcription factors required for late gene expression (step 6). The products of late gene expression encode most of the structural proteins as well as the viral transcriptase and associated factors that will be required at the start of a new infection. Progeny genomes, viral structural proteins, and membranes of the host cell participate in the assembly of viral particles that undergo extensive morphogenesis and maturation (step 7) prior to release.

FIGURE 5.8. Simplified replication scheme for hepadnaviruses. Following entry and partial uncoating (step 1), viral cores containing the gapped dsDNA genome migrate to the nucleus where the dsDNA genome is repaired and ligated into a covalently closed circle (steps 1 and 2). This repaired genome is transcribed by the host-cell RNA polymerase II (step 3) to yield terminally redundant pregenomic RNA and subgenomic RNAs for the viral structural and nonstructural proteins (step 4). In the cytoplasm, the viral DNA polymerase, reverse transcriptase (RTase), and core proteins associate with the pregenomic RNA to form immature cores (step 5) that mediate polymerase-primed reverse transcription of the pregenomic RNA to yield gapped dsDNA genomes (step 6). The progeny cores either then enter the nucleus (step 7) to repeat the cycle or can bud through the endoplasmic reticulum to yield viral particles (step 8).

Regulation of Viral Gene Expression

During the early, prereplicative phase of the infectious cycle of a typical DNA virus, a subset of so-called immediate early viral genes is expressed to produce mostly catalytic quantities of nonstructural proteins required for DNA replication and host-cell manipulation. After DNA replication, a different set of genes is expressed (late genes) that direct the synthesis of stoichiometric amounts of the structural proteins required for viral assembly. Expression of the early genes is often concomitantly repressed. This early/late switch, which is a common feature of many DNA virus families, can be understood as an evolutionary adaptation that gives viruses an advantage in competing with the host cell for gene expression: Early gene expression is modest, whereas later during the postreplicative stage of the infectious cycle, increased gene copy numbers enable the virus to dominate the protein synthesis capacity of the cell. In addition to the early and late genes, sets of intermediate genes have been identified in the poxviruses and herpesviruses, with each temporal class encoding factors that switch on the next in a transcriptional cascade (Figs. 5.6 and 5.7). For the viruses in these families, transcription factors for immediate early genes are expressed late in infection and assembled into progeny virions in preparation for the next infectious cycle.

At the start of infection, immediate early viral promoters face stiff competition from overwhelming numbers of cellular promoters. To successfully recruit RNA pol II and other components of the transcriptional machinery, many DNA viral genomes contain enhancers: *cis*-acting regulatory elements that facilitate the assembly of transcription complexes by binding multiple cellular transcription factors and other accessory proteins. A defining feature of enhancers, which were first identified in the genome of the polyomavirus simian vacuolating virus 40 (SV40), is that they exert their effects from either upstream or downstream of promoters and can act over distances of several kilobases.

Efficient transcription from late promoters usually requires one or more early gene products, as well as cellular transcription factors that may differ from those used by the early promoters. Dependence on specific cellular transcription factors can limit the expression of late genes to particular cells or tissues where the necessary factors are naturally expressed. For example, transcription of late papillomavirus genes requires a specific transcription factor that is expressed only in fully differentiated skin cells. As a result the replication cycle is stalled after DNA replication (Fig. 5.3, step 4) until the cell differentiates.

Infection of cells with herpesviruses and poxviruses increases the rate of mRNA degradation.¹⁹ In some herpesviruses, that is mediated by a protein component of the infecting virions called vhs (virion host shutoff). Although enhanced turnover is not specific for cellular mRNAs, viral mRNAs are readily replenished by robust transcription of the viral genome so that the net result is the selective suppression of host protein synthesis. In addition, the rapid turnover of viral mRNAs accelerates the transitions in the transcriptional cascade.

Mechanisms of DNA Replication and Transcription

Most DNA viruses produce functional viral mRNAs by usurping the transcriptional machinery of the cell (Fig. 5.1). This

machinery includes RNA pol II, multiple transcription factors, poly(A) polymerase, guanylyltransferase, methyltransferases, and the pathway of mRNA export from the nucleus. Even viruses with unusual genome structures such as parvoviruses and hepadnaviruses use these cellular components because their genomes are rendered into dsDNA before transcription (Figs. 5.4 and 5.8). Only DNA viruses that replicate in the cytoplasm (pox-, irido-, and asfiviruses) use virus-specific enzymes for transcription and posttranscriptional modification of their mRNAs (Fig. 5.7). Because these enzymes are virion structural components, they can often be purified more readily than their cellular counterparts, and in the case of the vaccinia poxvirus and Chlorella virus, their reactions and structural properties have been well studied.^{45,51,53} The majority of RNA viruses also replicate in the cytoplasm and employ virus-specific enzymes to synthesize and modify their mRNA.²⁴

Viral DNA genomes replicate by at least five different mechanisms, which are summarized as follows (for more details readers are referred to the chapters that describe each viral family).

1. The circular dsDNA genomes of polyomaviruses and papillomaviruses (Fig. 5.3) replicate bidirectionally from a single AT-rich origin via the RNA-primed synthesis of continuous leading strands and discontinuous lagging strands at both replication forks. Circularity of the genome aside, the reactions at the replication forks closely resemble how the host chromosome is replicated.^{35,68}
2. In stark contrast, the linear dsDNA genome of adenoviruses (Fig. 5.5) is replicated by a protein-primed synthesis of only the leading strand, resulting in displacement of ssDNA from each end of the parental duplex. The termini of the displaced strands anneal via inverted terminal repeats, creating duplex panhandle structures that serve as secondary origins of replication. The primer (preterminal protein) is the product of an early gene, and a copy of this protein is covalently bound to the 5' end of each of the daughter strands.^{23,67}
3. The linear dsDNA of herpesvirus genomes is first circularized and then replicated from one or more internal origins, most likely by an RNA-primed mechanism that eventually produces dsDNA concatamers (Fig. 5.6). Progeny DNA can undergo isomerization by homologous recombination between internal and terminal repeated sequences, and unit length genomes are resolved from the concatamers during packaging into virions.⁷⁵
4. Despite their different structures and sizes, poxvirus (Fig. 5.7) and parvovirus (Fig. 5.4) genomes replicate by similar mechanisms. The close-ended duplex poxvirus genome (or the closed-ended duplex intermediate in parvovirus replication) is nicked near its terminus, and the newly generated 3' end serves to prime DNA synthesis using the complementary strand of the duplex as template. This initial self-priming event is reproduced by partially base-paired hairpin structures located at each end of the duplex genome, resulting in so called "rolling hairpin" replication. For both poxviruses and parvoviruses, the product is a dsDNA concatamer from which unit length genomes are excised by resolution of concatamer junctions.^{9,20,104}
5. Finally, in the most tortuous mechanism of all, hepadnaviruses (Fig. 5.8) replicate their dsDNA genome by a

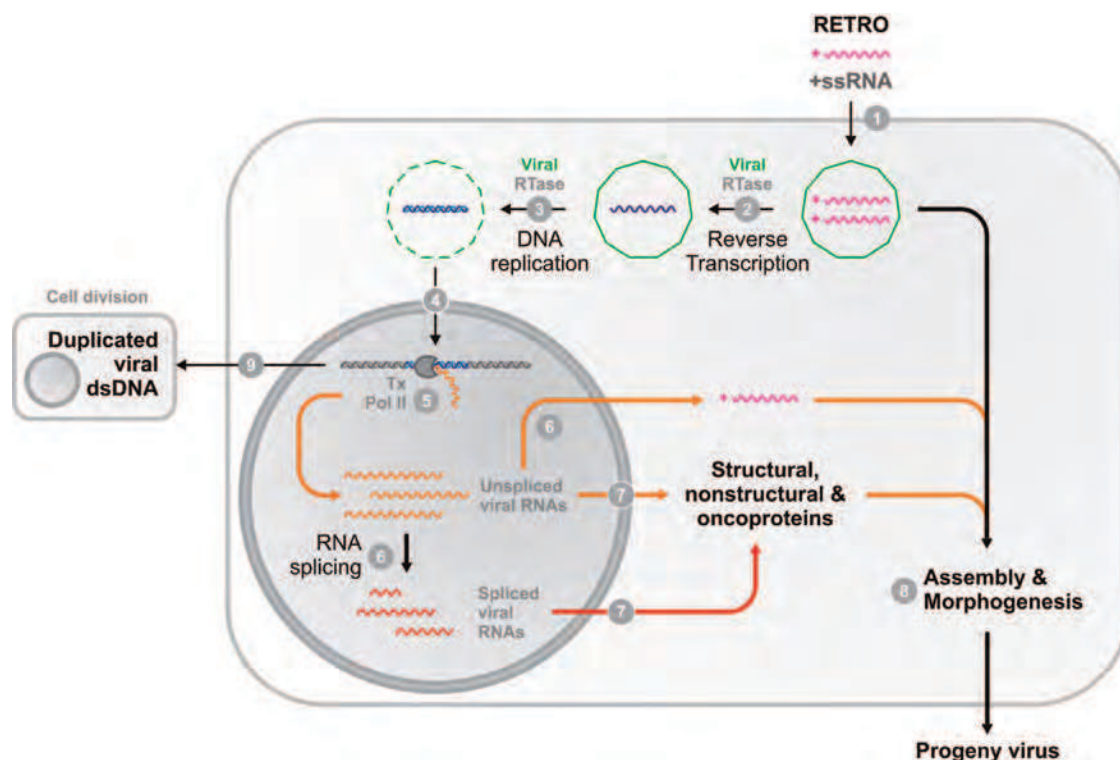

FIGURE 5.9. Simplified replication scheme of *Retroviridae*. Following entry and partial uncoating (step 1), the viral genome is copied into dsDNA by the reverse transcriptase (step 2 and 3) and integrated into the host chromosome by the virion DNA integrase (step 4). The integrated viral genome (provirus) is transcribed by the host-cell RNA polymerase II (step 5) to produce viral transcripts that function as precursors to the mRNA for the viral proteins (steps 6 and 7) as well as progeny genomes for assembly into infectious particles (step 8).

full-length pregenomic ssRNA transcript made by RNA polymerase II. Pregenomic RNA is then reverse transcribed by the viral encoded DNA polymerase/reverse transcriptase to produce dsDNA progeny. In contrast to retroviruses (Fig. 5.9), DNA integration is not required for hepadnavirus replication, the genome being maintained as a circular episome in the nucleus of infected cells. Caulimoviruses—the only dsDNA viruses that infect plants—use a similar reverse transcriptase (RT)-mediated replication strategy. To prime first strand DNA synthesis, hepadnavirus RTase uses a domain of the polymerase itself. This differs from the tRNA-primed strategy employed by retroviruses and caulimoviruses.

The polymerases employed for these strategies of replication are structurally and functionally homologous—yet they accomplish replication via very distinct mechanisms. Thus the evolutionary origin of such disparate mechanisms of replication remains uncertain.

Remarkably protein-primed replication is discontinuous. In the three known examples—adenovirus, poliovirus, and hepadnaviruses—the first few nucleotides of the genome are templated from an internal motif rather than at the very 3' end of the parental genome. This necessitates a jump or realignment of the protein-primer product together with the polymerase to the 3' end of the parental genome to complete

synthesis of the daughter strand. In the case of adenovirus, the first templated nucleotides added to the primer are positions 4–6 of the genome, which then realigns with the 3' end of the genome to complete daughter-strand synthesis following annealing of the nascent strand to the first three nucleotides of the parental genome.²³ For hepadnaviruses, the first four nucleotides are added to the RTase from a stem loop positioned at the 5' end of the pregenomic RNA. The RTase nascent strand RNA product leaps almost 3 kb and then continues processively to complete synthesis of the daughter strand. Among the RNA viruses, the picornaviruses employ an internal stem loop termed the *cis*-acting replication element (cre) within the parental strand to template the uridylation of a protein primer, VPg.⁸² This primer is then repositioned together with polymerase at the 3' end of the genome to prime synthesis of the new strand. Such protein-primed mechanisms likely aid in maintaining the integrity of the genome ends, which contain vital signals for replication.

Latent and Persistent Infections

In addition to the typical vegetative replication cycles illustrated in Figures 5.3 through 5.8, many DNA viruses establish latent or persistent infections of their hosts. Several distinct mechanisms of persistence have been identified with different viruses, but they all involve suppression of viral cytopathic effects,

long-term maintenance of the viral genome, and evasion of the cellular and organismal defences. For example, herpesviruses typically establish latent infections in which the viral genome is maintained as a circular episome in the nucleus, expressing at most only a few viral genes and yielding no infectious virus. Such latent herpesvirus infections persist throughout the life of the host, successfully evading host immune surveillance, yet able to reemerge at intervals as productive lytic infections. Because of its importance for human health, understanding the establishment and maintenance of herpesvirus latency and the mechanisms that regulate the reemergence of infectious virus are the subject of intense study (see Chapters 59 to 65). In the case of human herpesvirus 4 (Epstein-Barr virus), which infects B lymphocytes and causes mononucleosis, latent infections can be established and maintained in cell culture; this has greatly facilitated experimental study of the mechanisms involved. For other herpesviruses, the establishment and maintenance of latency occur in less-accessible cell types and are much less well understood.

Viral Oncogenes and Neoplastic Transformation

In cells that somehow survive DNA virus infection, such as nonpermissive cells that express early genes but cannot replicate viral DNA or produce infectious progeny, the expression of viral oncogenes and the consequent loss of cell cycle control can lead to neoplastic transformation and the formation of tumors in infected animals (see Chapter 7). Unlike typical retrovirus-induced tumors, where the entire viral genome is integrated into the host chromosome as an essential step of

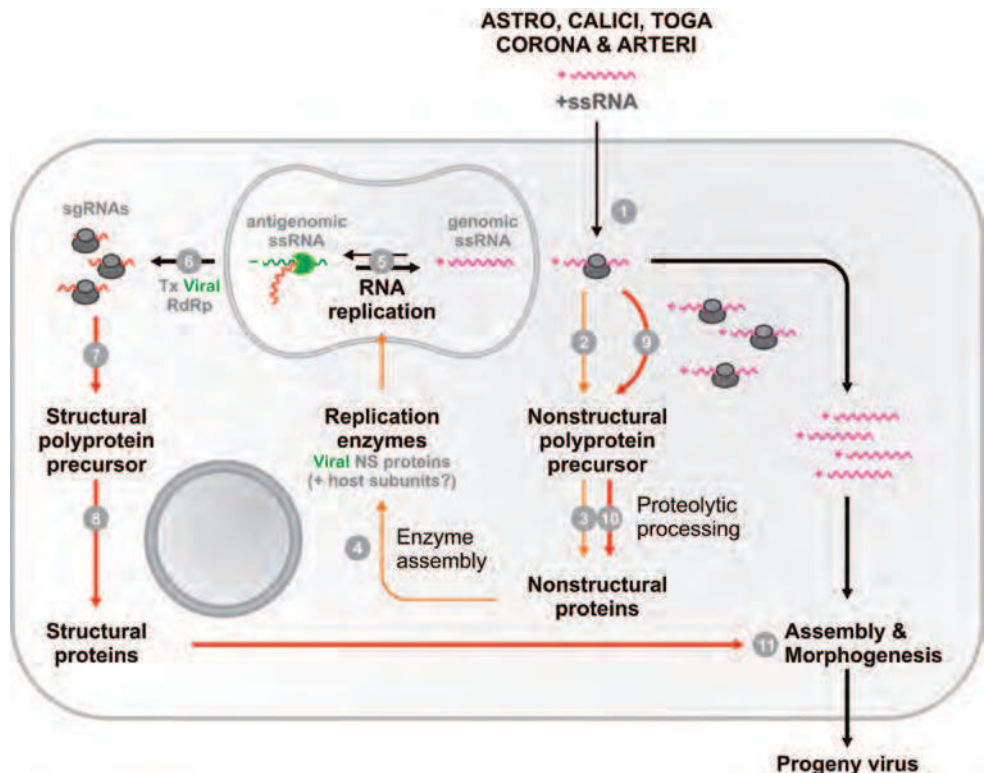

the viral replication cycle, tumors induced by DNA viruses rarely contain a complete viral genome or produce infectious virus. Instead, they typically express only the viral oncogenes from integrated copies, disrupting cell cycle control by inactivating p53/pRb or by activating cyclin-dependent kinases, for example. Alone among the DNA viruses that replicate in the nucleus, parvoviruses do not induce tumors because they are unable to override cell cycle controls. Some poxviruses induce the formation of self-limiting benign tumors when they secrete a virus-encoded growth factor that induces surrounding cells to divide.

EXPRESSION AND REPLICATION OF RNA VIRUS GENOMES

RNA Virus Genome Strategies

The type of RNA genome dictates the first biosynthetic steps following infection. For example, the message sense positive-strand RNA viruses, excluding the retroviruses, all initially deliver their genomes to ribosomes to ensure the synthesis of essential proteins to establish viral replication (Figs. 5.10 and 5.11). Consequently the viral genomic RNA alone is infectious once delivered into a host cell—a fact that greatly facilitated the genetic manipulation of such viruses. That the RNA alone was infectious was first shown for tobacco mosaic virus, in experiments that helped establish that genes were comprised of nucleic acids.⁴¹ By contrast to the genomes of positive-sense RNA viruses, those of the negative-strand RNA viruses, retroviruses, and double-stranded RNA viruses all must deliver into

FIGURE 5.10. Simplified replication scheme of positive-strand RNA viruses that produce subgenomic RNA. Following entry and uncoating (step 1), the genomic RNA is engaged by the host-cell ribosome to produce the nonstructural proteins including the RdRp (steps 2 and 3). The viral replication enzymes together with host components form replication compartment in which the genomic RNA is replicated into an antigenome and progeny genomes (steps 4 and 5). The viral RdRp also transcribes one or more subgenomic RNAs (step 6) that encode viral structural proteins (steps 7 and 8). Replicated genomes are translated to amplify the production of viral proteins (steps 9 and 10) and may be used as templates for further replication. The genomes are assembled with viral structural proteins (step 11) to yield progeny virions. The scheme by which the *Coronaviridae* and *Arteriviridae* synthesize their subgenomic RNA is different from that employed by the *Toga*-, *Astra*-, and *Caliciviridae*.

FIGURE 5.11. Schematic of the replication cycle of positive-strand RNA viruses that do not make subgenomic RNA. Following entry and uncoating (step 1), the genomic RNA is used directly as an mRNA to synthesize both structural and nonstructural proteins (steps 2 and 3). The nonstructural proteins, including the RdRp and host components, establish a membrane-associated replication compartment in which the genomic RNA is copied into antigenomic RNA and progeny genomes (steps 4 and 5). Replication produces additional genomic RNA that can be used for further translation and genomic amplification (steps 6, 7, and 5) as well as assembly with the viral structural proteins (step 8) to yield progeny virions.

the cell a protein RNA complex that contains within it the viral polymerase.

The positive-sense RNA viruses fall into two general groups, those that transcribe subgenomic RNAs (Fig. 5.10) and those that do not (Fig. 5.11). Viruses that do not transcribe subgenomic RNA are translated by the host ribosomes to produce one or more polyprotein precursors that undergo a set of *in cis* and *in trans* cleavage reactions by viral encoded proteases.²⁹ Those cleavage reactions result in the production of the individual non-structural proteins essential for the replication of the viral genome, including the establishment of the site of viral replication. For viruses that produce a single polyprotein the precursors of the catalytic components are generated in equimolar amounts to the structural proteins. In some cases, control over the abundance of the catalytic components is provided by the accumulation of intermediates in the processing cascade in which one or more of the catalytic activities are absent.⁹⁵ Such components can play crucial structural or regulatory roles in the establishment of replication compartments. Viruses that produce two polyprotein precursors always employ an internal ribosome entry site (IRES) to drive the expression of the second polyprotein. Because the translation of the second polyprotein is independent of the first, the proteins are not produced in equimolar amounts, allowing for some regulation of the abundance of the different proteins.⁵⁰ For viruses that produce subgenomic RNAs, the input genome is first translated into a precursor of the nonstructural proteins that includes the RdRp. The genome is then subsequently copied into one or more subgenomic mRNAs that encode the

structural proteins. The production of subgenomic mRNAs facilitates the synthesis of distinct amounts of the structural and nonstructural proteins—such that the structural proteins are often produced in vast molar excess of the catalytically essential nonstructural proteins.

In contrast to the naked RNA of the positive-sense RNA viruses, that of the negative-sense, ambisense, and dsRNA viruses is noninfectious (Figs. 5.12–5.14). This is because the infectious unit is a ribonucleoprotein complex comprising the genomic RNA associated with the necessary viral polymerase components for synthesis of mRNA.^{76,105} In the case of the negative-sense and ambisense RNA viruses, the input genomic RNA is copied by the viral polymerase complex into mRNA (Figs. 5.12 and 5.13). The input genomes are then replicated to yield antigenomes, a process that requires newly synthesized viral nucleocapsid protein to coat the nascent RNA strand.^{76,105} For the negative-sense RNA viruses (Fig. 5.12), the antigenomes are positive sense, but they do not serve as templates for translation, rather they function exclusively as templates for genomic replication.^{76,105} The negative-sense orthomyxoviruses and bornaviruses replicate within the host-cell nucleus, whereas the mammalian infecting rhabdoviruses as well as the paramyxoviruses and filoviruses replicate in the cytoplasm. A further important distinction is that the rhabdo-, filo-, paramyxo-, and bornaviruses sequentially transcribe a series of 5 to 10 monocistronic mRNAs from a single genomic template, whereas the orthomyxoviruses synthesize only a single mRNA from each segment. In the case of the ambisense RNA viruses, the genomic and antigenomic RNAs have both message and

FIGURE 5.12. Simplified replication scheme for negative-sense RNA viruses.

Following entry and partial uncoating (step 1), the encapsidated viral genomic RNAs are transcribed by the virion RdRp into mRNAs (step 2) that encode the viral structural and nonstructural proteins (step 3). For the *Orthomyxoviridae* and *Bornaviridae*, transcription occurs in the nucleus (reflecting their need for splicing), whereas for the *Rhabdo*, *Filo*, *Paramyxo*, and *Bunyaviridae* this occurs in the cytoplasm. Replication is concomitant with encapsidation of the genomic and antigenomic RNAs (steps 4 and 5), and the newly produced genomic RNAs serve as templates for further mRNA production (step 6) as source of further viral proteins (step 7) as well as for assembly of progeny virions (step 8). The segmented negative-sense RNA viruses transcribe each genomic segment into a single transcript (which can be alternately spliced in the case of the orthomyxoviruses). The non-segmented negative-sense RNA viruses sequentially transcribe a series of 5 to 10 monocistronic mRNAs from the genomic template.

FIGURE 5.13. Replication scheme for the ambisense RNA viruses.

Following entry and partial uncoating (step 1), the encapsidated genomic RNAs are transcribed by the virion RdRp to yield mRNAs (step 2) that encode the viral nucleocapsid protein and RdRp (step 3). These proteins catalyze the synthesis of antigenomic RNA (step 4), which serves both as templates for transcription of additional mRNAs (step 5) that encode the remaining viral proteins (step 6), as well as templates for production of more genomic RNA (step 4). The replication products (both genomic and antigenomic) can serve as further templates for transcription of mRNA that encode both viral structural and nonstructural proteins (steps 5 through 8). The genomic RNAs are also assembled together with the structural proteins into infectious viral particles (step 9). Note some bunyaviruses are also simply negative-sense.

FIGURE 5.14. Simplified replication scheme for dsRNA viruses. Following entry and partial uncoating (step 1), the dsRNA segments within viral cores are transcribed by the core associated RdRp to produce mRNA (step 2) for the viral proteins (step 3). These form subviral particles around the mRNA (step 4), which are then copied to produce genomic dsRNAs (step 5). RNA synthesis and replication likely occur within a specific cytoplasmic factory established by the viral proteins. Progeny subviral particles contribute to viral gene expression (steps 6 and 7) and replication (steps 8 and 9) and assemble with outer shell proteins to form progeny virus particles (step 10).

anti-message polarity. However, those RNAs serve exclusively as templates for both mRNA transcription and replication (Fig. 5.13) rather than translation.³⁴ In contrast to all other negative-strand RNA viruses, the circular ssRNA genome of HDV does not require a specialized viral polymerase for copying. Rather, the HDV genome is transcribed and replicated by the host DNA-dependent RNA polymerase II in a unique RNA-templated reaction.⁹⁷

For the dsRNA viruses, the segmented genomes are delivered into the cell as a subviral particle that remains intact for transcription of the mRNA (Fig. 5.14). The polymerase and RNA-modifying enzymes form a structural element through which the nascent ssRNA strand passes and is cotranscriptionally modified. The ssRNA and their encoded proteins reassemble into new subviral particles that can direct the synthesis of antigenome RNA and form a dsRNA genome. Those progeny subviral particles can serve as templates for the production of further mRNA, and the viral protein or can be packaged into new virions.⁶⁹

The positive-sense RNA genomes of retroviruses (Fig. 5.9) use a distinct mechanism for replication. Here, the incoming ssRNA is copied into a dsDNA provirus using the virally encoded reverse transcriptase—an essential component of the incoming virion.^{5,98} This dsDNA is integrated into the host genome, where it is copied into differentially spliced transcripts that either serve as template for production of viral proteins or for production of viral progeny.

Regulation of Gene Expression

In contrast to DNA viruses, which exhibit clearly demarked early/late-phase gene expression, most RNA viruses show little differentiation between the pre- and postreplicative phases of the infectious cycle, and express their genes at roughly the same relative levels throughout infection. In cases such as the togaviruses and orthomyxoviruses (e.g., the influenza viruses) where some temporal regulation of gene expression occurs, the differences are subtle and mostly accompanied at the transcriptional level by modulation of mRNA levels.

Although DNA viruses utilize alternate translational control mechanisms as well as RNA viruses, translational control is especially prevalent among RNA viruses. The rate-limiting step for translation of cellular mRNA by the ribosome is at the process of initiation, and more specifically recognition of the mRNA cap structure by the cap-recognition protein eIF-4E, part of a multi-subunit complex. The cap-recognition complex then facilitates the recruitment of the small subunit of the ribosome in complex with other initiation factors. This complex then scans to the first AUG on the template RNA, typically localized within 100 or so nucleotides of the mRNA cap structure. Following this scanning to the AUG, the small subunit is joined by the large ribosomal subunit, and polypeptide chain synthesis is initiated. The poly(A) tail present at most cellular mRNA structures stimulates translation, as it is bound by the poly(A)-binding protein that bridges interactions with

the eIF-4G component of the cap-recognition complex. This may serve to functionally circularize the mRNA to facilitate ongoing translation. There are many notable exceptions to this general mechanism that have been exploited by RNA viruses. This reflects the fact that although superficially many RNA virus positive-sense transcripts resemble cellular mRNAs, there are distinctions at both the 5' and 3' ends of the RNA that are accompanied frequently by an altered mechanism of translational initiation.

One of the best known examples of an altered mechanism of translational initiation was provided by studies of how the genomes of picornaviruses—which lack a 5' mRNA cap structure and instead contain a genome-linked protein VPg—are expressed. The 5' untranslated regions of picornavirus genomes are unusually long (several 100s of nucleotides, including several AUG-specifying triplet) and are highly structured. Those structured elements termed internal ribosome entry sites (or IRES) serve to recruit the ribosome directly to the viral RNA,⁸³ without the need for a full complement of initiation factors for translation. Indeed in some viruses, such as cricket paralysis virus, the ribosome is recruited to the IRES without the need for any of the initiation factors that are essential for conventional translation. Such altered mechanisms are exploited by viruses to facilitate the efficient translation of the viral mRNA, thereby outcompeting cellular transcripts for translation ensuring the robust synthesis of viral proteins.

There are also many RNA viruses that produce mRNAs that lack a polyadenylate tail, the dsRNA reoviruses and rotaviruses, many of the ambisense arenaviruses and bunyaviruses, as well as numerous positive-strand RNA viruses. On most cellular mRNAs, the polyadenylate tail is generally thought to function as an element that stabilizes the mRNA and additionally favors translation by facilitating recycling of ribosomes through a protein-mediated bridging mechanism that brings the 5' and 3' ends of the mRNA together. Such circularization is likely achieved by direct RNA–RNA interactions in the case of some positive-strand RNA plant viruses—such as the luteovirus, barley yellow dwarf virus.⁵⁸ A similar mechanism has been postulated to function for the flavivirus, Dengue virus, although direct evidence for this is lacking.

A further mechanism of regulation of translation initiation exploited by RNA viruses is a translation termination–reinitiation strategy. This strategy involves the termination of translation of an upstream open-reading frame followed by the reinitiation at a proximal (<40 nt away) downstream open-reading frame. The stop and start codons are frequently found in an overlapping arrangement, but in distinct reading frames to one another, and termination is essential for the subsequent reinitiation. This strategy is exploited by the positive-strand RNA calciviruses, such as feline calicivirus and murine norovirus; as well as the negative-strand RNA viruses influenza B virus and respiratory syncytial virus.⁸⁶ Although the mechanism is not well understood, evidence from studies of calicivirus translation implicates the presence of a secondary structure in the mRNA that may function to “tether” the small ribosomal subunit to the transcript before reengagement of the large subunit.

Suppression of termination is also exploited during the translation of many viral mRNAs, notably those of the alphavirus and retrovirus families, as a mechanism of producing a protein with an extended C-terminus. In the case of some

retroviruses, a *cis*-acting regulatory element at the Gag-Pol junction functions to suppress termination of translation by leading to the misreading of the UAG termination codon to form the Gag-Pol polyprotein. Processing of this polyprotein then provides the viral reverse transcriptase and integrase. A second strategy is used by Rous sarcoma virus as well as other retroviruses, termed ribosomal frameshifting. A slippery sequence in the template leads to a realignment of the tRNA and the subsequent accessing of an altered reading frame. Such a mechanism is also exploited by other positive-strand viruses (notably the *Coronaviridae*) as well as several DNA viruses.

Structural and Nonstructural Proteins

By definition, virus-specified structural proteins are incorporated into virus particles, whereas nonstructural proteins are found only in infected cells. However, negative-sense, ambisense, and dsRNA viruses assemble their RdRp's and associated enzymes into progeny virions and therefore encode predominantly or exclusively structural proteins. In addition to the polymerase, virus-encoded enzymes often include one or more proteases, an RNA helicase, guanylyltransferase and methyltransferases, poly(A) polymerase, sometimes a nuclease, and in the case of retroviruses, a DNA integrase. However, for several RNA viruses, the evidence that these enzymes are virally encoded is only circumstantial or based on inconclusive sequence homologies.

The proteases process the primary translation products of which they are a part by cleaving them at highly specific target sequences, and in some picornavirus-infected cells they also selectively inhibit host-cell protein synthesis by cleavage of the eIF-4G component of the cap-recognition complex. Particularly among the larger RNA viruses, RNA helicases may be required to disrupt intermolecular or intramolecular base pairing during RNA synthesis, although some RdRp's are capable of melting RNA duplexes without help. Guanylyl and methyltransferases construct the 5' caps found on the mRNAs of most eukaryotic RNA viruses,^{24,37} except for the picornaviruses, which are uncapped, and the orthomyxoviruses, arenaviruses and bunyaviruses, which acquire their caps by stealing them from the host using a virus-encoded cap-dependent endonuclease.^{72,85} The cap structures of the *Mononegavirales* are formed by an altered mechanism involving a guanosine diphosphate (GDP)—polyribonucleotidyltransferase that is found within the same polypeptide chain that contains the polymerase and mRNA cap methylase activities.^{65,66,77,78} At their 3' ends, most animal virus mRNAs carry untemplated poly(A) tails, although 3' tRNA-like structures are common among plant RNA viruses (see Chapter 72). Polyadenylation is usually ascribed to a stuttering side reaction of the viral RdRp rather than to a separate poly(A) polymerase, as found in poxviruses, although the enzymology of the reaction remains to be clearly defined.^{76,105}

Comparisons among the amino acid sequences of viral RdRp's establish clear phylogenetic relationships that also reflect other differences in viral genome structures and strategies. Moreover, the x-ray crystal structures of the polio-, hepatitis C, reo-, rota-, phi6- and other RdRp's show clear resemblance to one another as well as to reverse transcriptases and DNA-dependent RNA and DNA polymerases. Although

the overall levels of amino acid sequence homology among these diverse polymerases are statistically insignificant, RdRp's share many of the characteristic polymerase motifs that occupy critical positions in the three-dimensional architecture of the polymerase active site. Taken together the structural similarities of their RdRp's firmly anchor the RNA viruses to the rest of the biosphere, and suggest that despite their diversity these viruses probably escaped from cellular origins to establish a horizontally transmissible parasitic existence using polymerases that radiated from a common ancestor.

Host Cell Factors

Proteins provided by the host undoubtedly play essential roles in RNA virus replication, although different cellular proteins have been implicated in different virus systems. The clearest example comes from the RNA replicase enzymes of the RNA bacteriophages Q β and MS2, which, in addition to the single phage-specified polypeptide that provides the polymerase active site, contain four cell-specified subunits: the *Escherichia coli* ribosomal protein S1, two translation elongation factors (EF-Tu and EF-Ts), and a strand-specific RNA-binding protein, host factor 1.⁸ In view of the similarity of their host components, the distinct specificities of the Q β and MS2 replicases for their cognate RNA templates must be determined by their unique viral subunits. The unexpected recruitment of translation factors to assist RNA replication—despite the evident differences between these two processes—may reflect underlying biochemical similarities in the RNA–protein interactions involved.

Translation factors have also been implicated in the replication of RNA viruses of eukaryotes. For example, a subunit of the initiation factor eIF-3 binds to the brome mosaic virus RdRp and increases its activity,⁸⁷ and several other host proteins have been found to associate with viral RNAs in infected cells. One of the difficulties in definitively assigning whether such proteins are just passengers, or active players in the replication of the viral genome, is often the lack of *in vitro* replication assays and/or genetically tractable host systems. Substantial progress has been made in this regard with the use of genetic, chemical, RNAi, as well as proteomic screens to hunt for host factors that are required for viral replication. Reconstructing the replication cycle of viruses in yeast,^{54,79} has permitted screens in collections of gene knockouts in *Saccharomyces cerevisiae*, and the application of RNAi has extended such screens to invertebrate and vertebrate cells.¹⁷ More recently the use of haploid human cells and gene-trap retroviruses has allowed the discovery of host-cell factors that are essential for the entry into cells of a number of viral pathogens.^{13,14} Although in some cases the overlap of “hits” between seemingly similar screens is low—likely reflecting technical difficulties of such large scale screens—the convergence on specific pathways exploited by viruses for their replication is generally high.⁴² Such systematic analyses provide a potentially fertile source for understanding the virus–host relationship; however, the detailed mechanistic understanding of how specific host proteins mediate viral replication lags behind.

In addition to host proteins, host nucleic acids also appear to participate directly in the replication of some RNA viruses. One such example is provided by host micro RNA's that function to titrate cellular gene expression by promoting transcript turnover or by sequestration. Work with hepatitis

C virus (HCV) identified a liver specific microRNA-122—which regulates cholesterol biosynthesis—that binds to two sites at the 5' end of the viral genome and enhances HCV replication.⁵⁵ Such control of viral replication only further serves to underscore the intimate relationship between viruses and their host cells.

Compartmentalization of Replication Sites

Unlike the phage replicases, the RdRp's of eukaryotic viruses are invariably found associated with some type of supramolecular assembly: host-cell membranes for positive-sense RNA viruses, nucleocapsids frequently found as inclusion-like structures for the negative-sense RNA viruses, and subviral particles arranged as factories for the dsRNA viruses. The positive-strand RNA viruses (Figs. 5.10 and 5.11) represent the best-characterized examples of membrane-associated replication complexes, with most information being available for the picornavirus and nodavirus families.²⁵ In most cases, the membranes are extensively rearranged, often—although not exclusively—derived from the endoplasmic reticulum, and invariable topologically arranged as an invagination of the membrane of the endoplasmic reticulum (ER) to form an open-necked crucible. Within each vesicle are a relatively small number of genomic templates—possibly as few as one, along with the viral replication machinery and cellular proteins that appear to play a role in the formation of the vesicular structure. The prevailing model is that such vesicular structures represent the sites of viral RNA replication, and that the nascent RNA chains are rapidly exported to the cytoplasm. In many cases, virion assembly sites are juxtaposed to such compartmentalized replication sites, which likely facilitates the coordination of the replication and assembly of viral particles. In the case of some positive-strand RNA viruses, notably the coronaviruses, the vesicles that are formed by the replication machinery appear to be closed from the cytoplasm. Whether specific viral protein(s), or a complex of viral and cellular proteins, are required to exchange nucleoside triphosphates and progeny genomes is not yet certain.

In the case of the negative-sense RNA viruses that replicate in the cytoplasm (Fig. 5.12), the viral replication machinery is typically found in inclusion-like structures that are often rich in cellular chaperones such as heat shock protein (hsp)70.⁶¹ Although such inclusion-like structures are not essential for RNA synthesis—as they are absent at the onset of infection and at a time at which the intracellular environment is likely most hostile for viral replication—such structures have been shown to be active sites of RNA transcription and seem to be sites of genome replication.^{48,61} Likewise, dsRNA viruses establish factories or viroplasms (Fig. 5.13) in the infected cell that are sites of RNA synthesis and assembly.¹⁰ Such compartmentalization of the replication machinery is therefore a conserved theme across a spectrum of viruses. Although it is clear that replication can occur in such sites, and this sequestration may both facilitate catalysis and sequester the viral replication machinery from surveillance by host defense machinery, it is largely uncertain what events lead to the establishment of such sites. Although there is a strong correlation between compartment formation and viral replication, examination of the very initial replication events including establishment of such sites remains challenging.

Mechanisms of RNA Replication and Transcription

The simplest mechanism of RNA replication is that used by HDV in which rolling circle synthesis by RNA polymerase II makes multimeric RNAs of both positive and negative polarity. *cis*-Acting ribozymes then cleave linear RNA monomers from these concatamers and covalently circularize them to produce mature antigenomes and genomes, respectively⁹⁷ (see Chapter 69). Although this simple mechanism is shared by several viroids and other subviral RNA pathogens of plants, HDV is the only RNA pathogen of vertebrates known to replicate by a rolling circle mechanism. Far more commonly, ssRNA genomes are replicated via the synthesis of complementary RNA monomers produced by successive rounds of strand displacement during end-to-end copying of linear templates.¹¹ However, both ends of the RNA are generally required for template activity, suggesting that even linear RNAs may be functionally circularized, perhaps to facilitate reiterative replication and hinder erosion of the termini.

The relative abundance of the genomic and antigenomic RNAs is regulated in different ways in different virus families. In the case of Q β , negative-strand RNA synthesis is limited by the requirement for an additional host subunit that is not required for positive-strand RNA synthesis.⁸ In other virus systems, distinct *cis*-acting RNA signals are largely responsible for determining the relative template activities of the complementary strands, although it is possible that different host factors are involved here as well. For the togavirus Sindbis, negative-sense RNA is synthesized only by a short-lived version of the RdRp, which is an intermediate in the proteolytic processing pathway of the viral nonstructural proteins.⁵⁶ As infection proceeds, increased viral protease activity cleaves this transient intermediate and thereby switches the template specificity of the RdRp to the synthesis of positive-strand RNA (see Chapter 22).

There are two general mechanisms of initiation by RdRp's: primer dependent and primer independent mechanisms. The majority of RNA viruses appear to employ a primer independent mechanism. Some of the best studied examples of this are provided by the bacteriophages Q β , MS2, and ϕ 6, as well as by eukaryotic viruses HCV, and reo-, rota-, and vesicular stomatitis virus. The general mechanism by which *de novo* initiation occurs is that the RdRp initiates synthesis by forming a phosphodiester bond between the initiation nucleoside triphosphate (iNTP) and a second NTP.¹² Atomic structures of polymerases engaged in the steps of initiation have provided remarkable insights into this process. The second general mechanism is a primer-dependent mechanism of initiation. The primers themselves can come in different flavors, for example, the picornavirus RdRp's use a small viral-encoded protein, VPg, that is covalently uridylylated by the polymerase on an internal RNA structure at a single A residue.⁸² This primer, polymerase complex then relocates to the terminus to prime the initiation reaction. Nucleic acids can also serve as primers for RNA synthesis, and here there are two currently known variations of this mechanism of primed initiation. The first of these is exploited by the RdRp's of the segmented negative-strand RNA viruses: *Orthomyxo*-, *Bunya*-, and *Arenaviridae* to prime messenger RNA synthesis. Here a virally encoded endonuclease cleaves a short capped primer from either host-cell pre-mRNA in the case of the *Orthomyxoviridae*, or mature cytoplasmic mRNA in the case of the *Arena-*

and *Bunyaviridae*.⁸⁵ Such primers then base pair with the ends of the template to prime synthesis of the viral mRNA. Remarkably the polymerases of those viruses also initiate "*de novo*". However, the available evidence supports that this reaction occurs not by initiation of synthesis opposite the terminal nucleotide, but by initiation at the penultimate nucleotide followed by a subsequent realignment of the nascent strand to "prime" the process of replication.³⁹ This strategy, termed "prime and realign" may help ensure the integrity of the termini are maintained during copying.

SUMMARY AND PERSPECTIVES

Mechanistic studies of viral replication have led us to some of the most fundamental discoveries in biology as well as provided critical knowledge to facilitate the development of vaccines and antiviral therapeutics to combat disease. The global burden of infectious disease caused by existing viruses and the ongoing threat of emerging viral infections further emphasizes the need to fully understand the mechanisms by which viruses replicate. Such studies promise to continue to uncover strategies to combat disease, and to harness viral replication for beneficial purposes both in the laboratory as expression vectors, gene knockout tools, neural circuit tracers, and probes of cellular, organismal, and population biology, but also in the clinic as potential vaccines, delivery vehicles, and imaging tools. The industrial applications of viruses are equally profound—as polymers, as well as tools to make microcircuits and even as potential fuel cells. All these applications of viruses have depended on our current understanding of the replication machinery and the strategies of viral replication. With the ability to simply manipulate viral genomes combined with the new burst in discovery of viruses from large scale sequencing projects, the future of fundamental studies of viral replication promises to be even more informative than the exciting past.

Virus assembly, a key step in the replication cycle of any virus, involves a process in which chemically distinct macromolecules are transported, often through different pathways, to a point within the cell where they are assembled into a nascent viral particle. A diversity of strategies and intracellular assembly sites are employed by members of the various virus families to ensure the efficient production of fully infectious virions. Nevertheless, a virus, irrespective of its molecular structure (membrane enveloped or nonenveloped) or the symmetry with which it assembles (icosahedral, spherical, or helical), must be able to take advantage of the intracellular transport pathways that exist within the cell if it is to achieve this goal. The end product of this selection process is assembly of each virus at a defined point within the cell. This chapter will focus on the cell biology of these intracellular targeting events, the intermolecular interactions that mediate targeting, and the assembly steps themselves.

Most viruses encode a very limited number of gene products. They therefore depend on the cell not only for biosynthesis of the macromolecules that constitute the virus particle but also for the pre-existing intracellular sorting mechanisms that

the virus utilizes to achieve delivery of those macromolecules to the sites of virion assembly. Because these are the same sorting mechanisms that the cell uses to delineate its subcellular organelles, the viral macromolecules must possess targeting signals similar to those of the components of those organelles. For a virus such as adenovirus, which assembles its nonenveloped capsids in the nucleus, this means that, following translation in the cytoplasm, each of the structural proteins of the mature virus must have the necessary protein-targeting information to be efficiently routed through the nuclear membrane to the assembly site. The situation is more complicated for a membrane-enveloped virus, such as influenza virus. For this virus, which assembles and releases virions from the apical surface of the epithelial cells that it infects, there is a necessity to ensure that the surface glycoproteins of the virus are correctly sorted by the secretory pathway of the cell to apical membranes. In addition, nucleocapsids, assembled in the nucleus, must be transported into and through the cytoplasm to the same location. As will be discussed later, the intracellular site at which the final phase of assembly and budding of an enveloped virus takes place is most often defined by the accumulation of the viral glycoproteins at a specific point in the secretory pathway of the cell. This also implies that there is specific molecular recognition of the virally encoded, membrane-spanning envelope components by the cytoplasmic nucleocapsids for a productive budding process to occur. Thus, interactions between proteins of viral and cellular origin, between viral proteins and nucleic acids and lipids, and between the viral proteins themselves are at the heart of the assembly process.

PARTITIONING OF PROTEINS WITHIN THE CELL

For an actively growing eukaryotic cell, there is a constant need to transport proteins and nucleic acids from their site of synthesis to the specific intracellular domains where they must function (Fig. 6.1). Proteins synthesized on cytosolic ribosomes, for example, must be transported to specific regions of the cytoplasm, to mitochondria and into the nucleus, whereas those synthesized on membrane-bound ribosomes will enter the secretory pathway and be targeted to specific organelles along the way. At the same time, messenger RNAs (mRNAs) and integral RNA components of the ribosome, or ribosomal RNAs (rRNAs), must be transported out of the nucleus. Proteins that participate in these intracellular trafficking processes have evolved to contain specific motifs that ensure the correct localization of the protein within the cell. Viruses have similarly evolved to take advantage of these pre-existing

FIGURE 6.1. Protein localization in a mammalian cell. Proteins destined for the plasma membrane traverse the secretory pathway of the cell. They associate with the endoplasmic reticulum co-translationally and are translocated across the ER membrane via a proteinaceous pore—the translocon. Proteins are transported from the ER to the Golgi complex and on to the plasma membrane unless they contain specific amino acid motifs that localize or retain them at an intermediate location. Transport from one compartment to the next is via coated vesicles. Some membrane-spanning (integral membrane) proteins contain endocytosis motifs in their cytoplasmic domain that facilitate incorporation into clathrin-coated endocytic vesicles. Such proteins can be sorted back to the plasma membrane, to the trans-Golgi compartment of the secretory pathway, or to a lysosome for degradation. Proteins destined for the nucleus contain nuclear localization signals. These are short amino acid sequences that allow interaction with the nuclear pore machinery for transport across the nuclear membrane. Some proteins shuttle between the nucleus and cytoplasm and contain in addition a nuclear export signal. ER, endoplasmic reticulum.

pathways to accumulate, in specific locations, the necessary components for assembly of a nascent virus.

Nuclear Import and Export of Proteins and Nucleic Acids

The Nuclear Pore Complex

The nucleus is segregated from the cytoplasm by an inner and outer membrane; thus, access to and egress from this subcellular domain is mediated by specialized structures termed *nuclear pore complexes* (NPCs).²⁰² There are approximately 3,000 NPCs on the nuclear envelope of an animal cell, and each provides a proteinaceous channel between the nucleus and cytosol. The NPC itself is a very large structure, with a molecular mass exceeding 50 mDa that exhibits eightfold symmetry and is constructed of multiple copies of approximately 30 different proteins called *nucleoporins* (Nups). Negative stain and cryo-electron microscope reconstructions of these complexes reveal a 125-nm diameter core structure in which eight spokes in a radially symmetrical arrangement join to form three main rings surrounding a central channel of approximately 35 nm.³ Attached to both faces of the central framework are peripheral structures, cytoplasmic filaments, and a nuclear basket assembly, which interact with molecules that transit the NPC.⁵⁸ The

channel is filled with flexible, filamentous FG-Nups, which are characterized by regions of multiple Phe-Gly repeats and form a *virtual gate* restricting transport into and out of the nucleus.¹⁸¹ Small molecules and proteins may be able to passively diffuse through the NPC; however, it acts as a molecular sieve for macromolecules. Larger proteins and macromolecular assemblages must be actively moved through what is clearly a dynamic, malleable transporter structure that has the capacity to accommodate macromolecular complexes with diameters of up to nearly 35 nm.¹⁵⁴

Nuclear Localization Signals

Proteins that are actively transported into or out of the nucleus are characterized by the presence of amino acid motifs that allow them to interact with the nuclear transport machinery. For import into the nucleus, these motifs are termed *nuclear localization signals* (NLS) and for export, *nuclear export signals* (NES). NLS motifs, such as that first identified in the SV40 T antigen,⁹⁵ are not only necessary for nuclear localization of the proteins in which they are present but are also sufficient to actively direct large foreign proteins, such as β -galactosidase, into the nucleus. Although there is no conservation of sequence in different NLS motifs, they are generally short (<20 amino acids), rich in basic amino acids, and

A. Nuclear localization signals:

Simple:

Bipartite:

**B. Nuclear export signals:**

FIGURE 6.2. Nuclear localization and export signals. A. Nuclear localization signals (NLS) are the amino acid motifs that direct proteins into the nucleus. Simple NLS sequences, such as those present in the SV40 virus T antigen or polyoma virus VP2, often contain a proline residue followed by a stretch of basic residues. This short sequence can relocate large proteins such as β -galactosidase into the nucleus. Bipartite NLS sequences, such as those present in nucleoplasmin or the adenovirus polymerase, are characterized by two stretches of basic amino acids separated by a variable spacer sequence. These NLS sequences are recognized by import receptor molecules such as importin- α . **B.** Proteins that shuttle into and out of the nucleus, such as Rev, possess a second motif, the nuclear export signal. These motifs are characterized by a pattern of conserved leucine residues.

frequently preceded by proline residues (Fig. 6.2A). Some NLS, such as that in the adenovirus DNA-binding protein, are bipartite and require two separate short clusters of basic residues to be functional.²³⁸

To be exported from the nucleus, proteins contain an NES. This nuclear transport signal is also short (~10 amino acids) and contains a pattern of conserved leucines¹³⁴ (Fig. 6.2B). Some proteins, such as Rev of human immunodeficiency virus type 1 (HIV-1), possess both an NLS and an NES and appear to shuttle back and forth between the cytoplasm and the nucleus.¹²⁴

Nuclear Transport Pathways: In and Out

Nuclear import is a two-stage process. In the first stage, the newly synthesized NLS-containing protein interacts with cytosolic receptor proteins that then bind to phenylalanine-glycine (FG) repeat containing Nups (FG-Nups) that make up the filaments on the cytoplasmic side of the NPC - a process referred to as docking. This complex is then translocated, in an energy-independent process, through the nuclear pore into the nucleus, where the complex is disassembled, allowing the transported protein to become functional.

The best-characterized protein import receptor is importin- α (also named karyopherin- α). After binding its NLS-containing cargo, importin- α interacts with importin- β , which then mediates docking with the NPC.⁹⁸ Most nuclear transport receptors belong to one large family of proteins (karyopherins), all of which share homology with importin- β (also named karyopherin- β). Members of this family have been classified as importins or exportins on the basis of the direction that they carry their cargo. Importins and exportins are regulated

by the small guanosine triphosphatase (GTPase), Ran, which is highly enriched in the nucleus in its GTP-bound form. Importins recognize their substrates in the cytoplasm and transport them through nuclear pores into the nucleus. In the nucleoplasm, RanGTP binds to importins, inducing the release of their cargoes. In contrast, exportins interact with their substrates only in the nucleus in the presence of RanGTP and release them after GTP hydrolysis in the cytoplasm, causing disassembly of the export complex (Fig. 6.3).²⁰⁴ Thus, the directionality of transport is regulated by whether Ran is complexed with guanosine diphosphate (GDP) or GTP.

Active transport of large molecules in either direction across the nuclear pore involves interaction with the FG-Nups. The FG repeats in these filamentous proteins provide binding sites for the nuclear transport receptors as well as other molecules, such as nuclear transport factor 2 (NTF2), involved in this process. The exact mechanism by which the importin-cargo complex is carried through the nuclear pore is not known. It is likely, however, that the process involves a series of docking and release cycles with the FG-Nup proteins that make up the transporter machinery within the nuclear pore channel.^{199,202}

The Secretory Pathway of the Cell

Proteins of both viral and cellular origin that are destined for the outer membrane of the cell travel along a highly conserved route known as the secretory pathway. This complex series of membrane-bound subcellular compartments, through which proteins pass sequentially, includes the endoplasmic reticulum (ER), an intermediate membrane compartment, and the cis-, medial-, and trans-compartments of the Golgi apparatus

FIGURE 6.3. Nuclear import and export pathways. A protein bearing a nuclear localization signal is recognized and bound by importin- α . Importin- β binds to this complex and carries it to the cytoplasmic filaments of the nuclear pore, where together they mediate translocation of the protein complex into the nucleus in an energy-independent process. In the nucleus, Ran-GTP binds to the importin complex, and it dissociates delivering the protein cargo into the nucleus. Proteins destined for export out of the nucleus bind to exportin-1 via their nuclear export signal. This complex, together with Ran-GTP, binds to nucleoporins localized to the nuclear basket of the pore complex and initiates translocation into the cytoplasm. Once there, Ran-GTP is converted to Ran-GDP by a Ran-GTPase-activating protein (RanGAP-1), causing the cargo-exportin-1-Ran complex to dissociate, thereby delivering the cargo to the cytoplasm. GTP, guanosine triphosphate; GDP, guanosine diphosphate.

(see Fig. 6.1). Proteins that traverse this pathway, such as the envelope glycoproteins of viruses, enter via the ER. Insertion of proteins into the ER occurs during translation through a process termed *translocation*. The ER network of tubules and sacs defines a unique environment in which protein modification and folding can occur isolated from the cytoplasm. Because polyribosomes, in the process of translating proteins that are translocating into the secretory pathway, are bound tightly to the ER membrane, regions containing them are known as the rough ER.

Translocation

Translating ribosomes are directed to the ER membrane by a short sequence in the nascent polypeptide known as the signal sequence. In most proteins, this 15 to 30 amino acid sequence, which contains a core of hydrophobic amino acids, is located at the N-terminus of the protein. Shortly after the signal peptide emerges from the ribosome, it is bound by a ribonucleoprotein (RNP) complex known as the signal recognition particle (SRP). Binding of SRP transiently arrests any further translation and directs the ribosome to an SRP-receptor on the ER (Fig. 6.4). Both SRP and its receptor have GTP-binding components, and the presence of this nucleotide is essential for efficient targeting.¹⁸⁷

Following the initial docking of the translationally arrested complex, the ribosome becomes tightly associated with the ER membrane via the translocon—a gated, aqueous, protein

channel that spans the ER membrane. Concomitant with this process, the SRP and its receptor are released, the signal peptide is introduced into the channel, and translation resumes. The components of the translocon have been identified through biochemical approaches in mammalian cells and genetic approaches in yeast and are comprised of a heterotrimeric complex known as the Sec61p (composed of Sec61 alpha, beta, and gamma chains). Based on the crystal structure of the archaeobacterial Sec61 homolog, SecY $\beta\gamma$, this complex forms a 40 Å × 40 Å structure with a pore-like central cavity and a single potential lateral opening to allow transition of membrane-spanning domains into the lipid bilayer.^{195,239} Additional proteins (e.g., the translocating chain-association membrane or TRAM protein) are necessary for optimal translocation. It is unlikely that the central pore of the translocon ever allows free diffusion between the cytosol and the lumen of the ER, because these compartments are chemically distinct. A constriction in the channel appears to be plugged by a short helix, and widening of the constriction as well as displacement of the plug have been linked to conformational changes induced by SRP binding to the complex.²¹⁹ GRP78 (BiP), a member of the Hsp70 family of chaperone proteins located in the lumen of the ER, plays multiple roles in gating the channel and facilitating translocation. The chaperone is then poised to facilitate the folding of the nascent polypeptide chain as it emerges from the pore, although

FIGURE 6.4. Protein translocation into the secretory pathway. Translation of a protein destined for the secretory pathway proceeds until the signal peptide exits the ribosome. The SRP binds to the signal peptide and the ribosome and arrests translation. The ribosome-SRP complex moves to the ER membrane, where SRP binds to its receptor (SRP receptor). This interaction, with concomitant hydrolysis of bound GTP, releases SRP and mediates a tight interaction between the ribosome and a proteinaceous channel—the translocon. The release of SRP and binding of the signal peptide to components of the translocon induces a conformational change that widens a constriction in the channel and allows resumption of translation to occur. The chaperone protein, Grp78 (BiP), present in the lumen, is poised to facilitate the folding of the nascent polypeptide chain as it emerges from the pore. The signal peptidase complex removes the signal peptide co-translationally from those proteins that have a cleavable signal peptide. Secreted proteins will continue to traverse the translocon until they are completely located in the lumen of the ER. In contrast, for integral membrane proteins, translocation will stop following introduction of the hydrophobic anchor domain into the translocon, and transition into the lipid bilayer occurs through a single lateral opening in the pore. SRP, signal recognition particle; ER, endoplasmic reticulum; GTP, guanosine triphosphate.

this binding is not essential for translocation to proceed. The signal peptide, in those proteins with a transient N-terminal sequence, is cleaved from the rest of the polypeptide by a complex of five proteins called the *signal peptidase* shortly after it enters the lumen of the ER (see Fig. 6.4).

For secreted proteins, translocation of the polypeptide through the translocon continues until the entire protein is present in the lumen of the ER. In contrast, integral membrane proteins, such as the envelope glycoproteins of viruses, contain a stop-transfer, membrane-anchor sequence that is generally located toward the C-terminus of the protein. Following the translation of this short (~25 amino acids) and mostly hydrophobic sequence, the translocon undergoes a conformational change that allows the membrane-spanning domain to be associated directly with the lipid bilayer. The product of this process is a type I integral membrane protein (Fig. 6.5), such as the influenza virus hemagglutinin (HA), in which the N-terminal ectodomain is in the lumen of the ER and the C-terminus is in the cytoplasm. In some proteins, such as the influenza virus neuraminidase (NA), a longer N-terminal signal peptide also functions as the membrane anchor. In this case, the signal peptide is not cleaved from the polypeptide chain and the sequences C-terminal to it are translocated into the ER lumen, resulting in a type II orientation. Multiple membrane-spanning proteins, such as the M protein of the coronaviruses, appear

to possess hydrophobic sequences that are alternatively recognized as signal and stop-transfer sequences, and translocation of such proteins may involve multiple Sec61 heterotrimeric complexes.¹⁹⁵

Posttranslational Modifications

Protein Folding and Quality Control. Proteins enter the lumen of the ER in an unfolded state and the process of folding into a transport-competent conformation is facilitated by interactions with molecular chaperones and folding enzymes located there. This collection of proteins includes BiP, calnexin (Cnx), calreticulin (Crt), GRP94, and protein disulfide isomerase (PDI). In addition to assisting in folding the nascent molecules, these proteins retain incompletely folded molecules in the lumen and act as a quality control system for the secretory pathway.²⁰ Oligomeric proteins, such as the receptor/fusion proteins of enveloped viruses, also assemble into their quaternary conformation in this compartment. For many of these molecules, oligomerization appears to be a prerequisite for transport out of the ER.

Glycosylation. Most proteins that traverse the secretory pathway are modified by the addition of oligosaccharide side chains either to the amino group of asparagines (N-linked glycosylation) or through the hydroxyl group of serines or threonines (O-linked glycosylation). N-linked moieties are added co-translationally in the lumen of the ER, where mannose-rich

FIGURE 6.5. Protein topology. Proteins with type I orientation generally have a cleavable N-terminal signal peptide that is removed co-translationally from the nascent protein. The protein continues to be transferred into the lumen of the ER until a hydrophobic anchor sequence is translated and enters the translocon. Translocation then stops, and the protein transitions from the protein pore into the lipid bilayer. Thus, type I integral membrane proteins, such as the hemagglutinin of influenza virus, have their C-terminus in the cytoplasm and their N-terminus in the lumen of the ER (topologically equivalent to outside the cell). In type II proteins, such as the influenza virus neuraminidase, the signal peptide forms the membrane anchor domain; thus, at the end of translation, the C-terminal sequences are translocated into the lumen of the ER, leaving the N-terminus in the cytoplasm. For multiple membrane-spanning proteins, such as the M protein of the coronaviruses, translocation is initiated at the first signal peptide sequence and continues until the first anchor domain. It is reinitiated following translation of a subsequent signal sequence and stopped again following translation of a second anchor. The exact mechanism by which this is accomplished without dismantling the translocon at intermediate steps in the process is not understood. ER, endoplasmic reticulum.

oligosaccharides are transferred by oligosaccharyltransferase from a lipid (dolichol) carrier to asparagine residues present in NXS/T motifs (where X is any amino acid but proline) within the protein. Trimming of terminal glucose and mannose residues from the branched oligosaccharide occurs in the ER and is closely linked with the Cnx- and Crt-mediated quality control process.²⁰ Further trimming of mannose residues followed by addition of other sugars (N-acetylglucosamine, galactose, fucose, and sialic acid), to yield complex oligosaccharide structures, occurs in the Golgi complex. O-linked oligosaccharides are also added in this organelle.

Transport Through the Secretory Pathway

Transport of soluble and membrane-spanning proteins from one compartment of the secretory pathway to the next is mediated by the formation of coated membrane vesicles that travel to and fuse with the target organelle. Thus, once the process of protein folding and quality control has been completed in the ER, proteins are sequestered into these transport vesicles prior to transit to the Golgi complex. The processes of cargo protein selection, budding, targeting, and fusion are probably

all mediated by specific protein constituents that define the different transport vesicles involved in shuttling proteins between components of the secretory pathway.^{86,210} In the case of ER-to Golgi transport, the vesicles have coat protein complex II (COPII),⁴³ whereas retrograde transport of vesicles from the Golgi to the ER, as well as anterograde transport through the Golgi, is mediated by COPI coats.¹⁴⁹ Budding is initiated at specialized regions of the ER (transitional ER) when a small myristoylated protein (SAR1) is converted to the GTP-bound form, allowing it to bind to the membrane and recruit coat proteins (Sec23, Sec24, Sec13, and Sec31) in a stoichiometric manner.⁴³ Formation of the coat itself induces membrane curvature and vesicle budding. Sorting signals displayed on the cytosolic surfaces of transmembrane protein cargo direct it into COPII vesicles, in some instances through physical association of the Sec23/Sec24 components in a sorting signal-dependent manner.¹⁰⁰ Soluble proteins and transmembrane proteins lacking COPII sorting signals depend on a diversity of transmembrane adaptor proteins that can link them to the budding machinery. These include the endoplasmic reticulum–Golgi intermediate compartment-53 (ERGIC-53) and p24 family

of receptor proteins, as well as a set of multiple membrane-spanning ER vesicle (Erv14p, 26p, and 29p) proteins that can facilitate concentration of soluble proteins in COPII vesicles.⁴³

Membrane receptors that mediate docking of the transport vesicle with the target organelle are also incorporated into the coat and appear to define the specificity with which the cargo protein is delivered. Rab-GTPases and tethering proteins appear to play an important role in defining the initial vesicle-target interactions,^{79,210} whereas soluble N-ethylmaleimide-sensitive factor (Nsf) attachment protein receptors (SNAREs) are generally accepted to mediate the final stage of vesicle docking and the subsequent membrane fusion events that are critical to transport.^{16,79} A vesicle-specific SNARE (v-SNARE) interacts with a target-membrane-specific SNARE (t-SNARE) complex (generally comprised of three peptides) during this process. Two additional proteins, the Nsf and soluble Nsf attachment proteins (SNAPs), act to disassemble the complex following fusion, allowing the SNARE components to be recycled.^{79,86}

Protein Localization

Subcellular localization of proteins within the secretory pathway appears to be determined by a combination of sorting/targeting signals that mediate interactions with the coat complex for inclusion in a transport vesicle and retention signals that localize the protein to a specific compartment within the secretory pathway. Localization is enhanced by the interplay of anterograde and retrograde transport that allows retrieval of proteins inadvertently transported beyond their target location. The classical example of this is the KDEL peptide sequence found on soluble proteins that are localized to the lumen of the ER.¹³¹ Proteins containing this sequence are efficiently retrieved from the cis-Golgi by the KDEL receptor, which is incorporated into COPI vesicles for trafficking back to the ER. Similarly, membrane-spanning proteins localized to the ER have, at the C-terminus of the cytoplasmic domain, a dilysine (KKXX) COPI-binding motif, which ensures their efficient retrieval from the Golgi complex.⁸⁴ This type of motif is utilized by the primate foamy viruses to concentrate the envelope glycoprotein complex (gp80/gp48) in the ER/intermediate compartment (IC), where virus budding occurs.⁶⁶ For integral membrane proteins, retention signals often appear to be associated with the membrane-spanning domain(s) of the protein, as is the case for the coronavirus M protein, and may reflect preferred association with specific lipid compositions of the membrane within a particular component of the secretory pathway.

The Golgi Complex

The Golgi complex represents a unique organelle within the secretory pathway in that it is comprised of a series of membrane-bound compartments that are the sites for specific biochemical modifications to proteins and oligosaccharides, as well as locations where specific protein-sorting decisions are made. Proteins transported from the ER enter the Golgi complex via the cis-Golgi network and, after traversing the cis-, medial-, and trans-cisternae, exit via the trans-Golgi network.¹⁷⁹ Each of the compartments provides a spatially distinct site for maintaining an ordered set of enzymes involved in the process of oligosaccharide maturation. They are also the sites at which proteins undergo O-linked glycosylation, through the addition, at certain serines and threonines, of monomeric sugar residues. It is in the trans-Golgi

cisternae and trans-Golgi network where viral glycoprotein precursors, such as the Env polypeptide of the retroviruses, are cleaved to their mature forms through the action of members of the furin family of proteinases—enzymes that normally function to process cellular substrates such as polypeptide hormone precursors. This cleavage event is critical for the generation of a biologically functional glycoprotein and thus for virus infectivity.

INTRACELLULAR TARGETING AND ASSEMBLY OF VIRION COMPONENTS

Viruses can be nominally divided into two groups based on the presence or absence of a lipid bilayer envelope. The nonenveloped viruses can assemble in the cytoplasm or nucleus and generally, for those that propagate in animal cells, exhibit icosahedral symmetry (Chapter 3). For these viruses, the viral structural proteins and genomic nucleic acid must be targeted to or retained at the subcellular domain at which assembly occurs. Enveloped viruses, by their very nature, must acquire a lipid bilayer from one of the cell's membranes during the process of assembly. In some viruses, such as the herpesviruses and some retroviruses, this envelopment step takes place after the assembly of an intact capsid shell, whereas for others the processes of envelopment and capsid assembly occur concomitantly. Some viruses undergo transient envelopment and in some cases re-envelopment during the process of assembly.

For nonenveloped viruses, the tightly assembled structure of the icosahedral shell forms a protective coat that prevents degradation of the genome by environmental factors. For enveloped viruses, the integrity of the nucleocapsid structure is less critical because the membrane provides a barrier to external degradative enzymes.

Assembly of Nonenveloped Viruses in the Nucleus

Adenoviruses are nonenveloped icosahedral viruses, 70 to 100 nm in diameter, that have a protein shell surrounding a DNA core. The protein shell (capsid) is composed of 252 capsomeres, of which 240 are hexons and 12 are pentons. Each penton consists of a five-subunit base (polypeptide III) and a trimeric fiber (polypeptide IV) that extends out and away from the shell. The hexon capsomeres are comprised of trimers of three tightly associated molecules of polypeptide II (Fig. 6.6).

For a nonenveloped virus such as adenovirus, which replicates exclusively in the nucleus, there is a strong dependence on nuclear targeting/transport pathways to export newly synthesized mRNAs out of the nucleus and to import structural proteins back into the nucleus. Nuclear import of the major capsid protein—hexon or polypeptide II—depends on the involvement of a second adenovirus protein, the pVI (precursor) polypeptide, which acts as a nucleocytoplasmic shuttling adapter and provides the necessary NLS for transporting the hexon into the nucleus.²²⁹ Trimer formation, in turn, depends on yet another virus-encoded, chaperone-like protein—L4 100K—which transiently binds to the newly synthesized hexon monomer and mediates its association with two additional monomers.²⁴ Thus, the most abundant structural protein of the adenovirus capsid needs to interact with two additional virus-encoded factors to attain the correct tertiary structure and subcellular location for assembly.

FIGURE 6.6. Assembly pathway for adenoviruses. Following transport into the nucleus, the hexons and pentons are proposed to assemble into empty capsids (previously known as light intermediates of assembly) around scaffolding proteins. These nonstructural scaffolding proteins are lost on packaging of viral DNA, which is inserted into this structure via a packaging sequence at the left end of the genome. The mechanism of insertion appears to be similar to DNA phages and involves a portal complex. The pIV2a protein may represent the ATP-hydrolyzing component required to drive DNA through the portal structure in the procapsid. Heavy intermediate forms of the capsid probably represent those in which DNA packaging is incomplete and the DNA is fragmented. Precursor core proteins would be packaged into the empty capsid along with the genome to form immature virions. Proteolytic cleavage of the precursor proteins by the viral proteinase yields the mature virion. ATP, adenosine 5'-triphosphate.

The two other proteins that form the 12 vertices of the capsid—penton and fiber—appear to assemble independently in the cytoplasm. Mutations in the C-terminus of the penton that block assembly into pentamers do not prevent transport into the nucleus,⁹⁶ indicating that each monomer has an active NLS. In contrast, the fiber must form trimers to be efficiently transported to the nucleus,¹⁴⁶ even though this protein has an active NLS located at its N-terminus. It seems likely that the penton base and fibers are transported independently into the nucleus and assemble into the intact penton at the site of assembly.

Although two distinct pathways for adenovirus capsid assembly have been postulated from a large body of work in this area, it now appears that an empty procapsid is first formed around scaffolding proteins, in a manner similar to that observed with DNA phages. Results from experiments that combined kinetic labeling with temperature-sensitive replication mutants and additional site-directed mutants have yielded the assembly scheme shown in Figure 6.6. Several viral products appear to act as scaffolding proteins, around which shells are assembled and that facilitate the encapsidation process. These proteins are present in the intermediate capsid-like

particles but are absent once DNA has been encapsidated.³⁹ Disruption of adenovirus capsids with denaturants results in the release of groups of nine hexons that are associated with the faces of the icosahedron and lack the peripentonal hexons. Under acidic conditions, these nanomers can reassemble to form icosahedral shells that lack the 12 vertices, which would normally be composed of the penton and the five peripentonal hexons, raising the possibility that hexon nanomers are intermediates of adenovirus capsid assembly. Following procapsid assembly, DNA and associated core proteins are then subsequently packaged into these empty shells to yield immature virions that then undergo proteolytic maturation. Recent studies have demonstrated that the approximately six to eight copies of the pIV2a protein, which binds to the packaging sequence, are present at a single apex of the mature virion.²⁹ This, and the fact that the pIV2a protein contains motifs (the Walker A and B boxes) associated with the binding and hydrolysis of adenosine 5'-triphosphate (ATP), suggests that it may represent the ATP-hydrolyzing component required to drive DNA through a portal structure in the procapsid. Consistent with this, mutations that either prevent synthesis of pIV2a or prevent binding

of ATP to the protein block genomic packaging and result in the assembly of empty procapsids.¹⁵⁰

Assembly of Enveloped Viruses in the Nucleus

Two enveloped animal virus families—the herpesviruses and the orthomyxoviruses—utilize cell components that are located within the nucleus in their replication and initiate their assembly within that compartment. In addition to importing into the nucleus the necessary components for assembly, these viruses must also export large nucleoprotein complexes back out into the cytoplasm.

In some respects, the herpesviruses represent a hybrid between a nonenveloped virus, such as adenovirus, and a more conventional enveloped virus, such as a retrovirus, in that they utilize the compartments of the secretory pathway to transport large capsid structures from the nucleus to the outside of the cell. Members of this group of large viruses assemble, within the nucleus, an icosahedral capsid shell that is 160 Å thick and 1,250 Å in diameter. The major component of this protein shell is pUL19, which forms both the pentameric and hexameric capsomeres necessary to assemble the icosahedral structure. Associated with the outer surface of the hexamers is the abundant small protein pUL35. Two additional proteins—pUL38 and pUL18—in a 1:2 ratio, form heterotrimeric triplexes that fit between and link together adjacent capsomeres.¹⁴⁰ Scaffolding proteins are essential for herpes simplex virus type 1 (HSV-1) capsid assembly/maturation; in their absence, incomplete and aberrantly shaped capsids are assembled. As with adenovirus, the major capsid protein lacks a nuclear targeting signal, and its transport into the nucleus requires an interaction with either the scaffolding protein (pUL26.5) or the triplex protein pUL38, which presumably provide the necessary NLS. pUL18 similarly requires pUL38 for nuclear localization, whereas pUL35 appears to be directed there via its interaction with pUL19.¹⁷⁰

Studies of virus-infected cells together with *in vitro* assembly studies have provided valuable insights into the assembly process.^{123,142} These studies point to a pathway in which pUL19, pUL38, and pUL18 assemble around a scaffold to form an icosahedral but predominantly spherical procapsid—the *B-capsids* identified by electron microscopy. Although not required for capsid formation, in its presence the portal complex apparently initiates capsid formation leading to its incorporation into the nascent capsid.¹⁴¹ Cleavage of the scaffolding protein at a site near its C-terminus by the viral protease removes a 25 amino acid sequence that is necessary for binding to pUL19. The resulting disassociation and release of scaffold allows for packaging of the viral DNA genome and induction of maturation of the capsid into a more angular icosahedral structure, the previously identified *C-capsids*. DNA enters the procapsid through a unique vertex composed of the portal protein pUL6, which is assembled into rings composed of 12 subunits to form the portal complex.¹⁴³ The pUL6 portal resembles the connector or portal complexes employed for DNA encapsidation by double-stranded DNA bacteriophages such as ϕ 29, T4, and P22. In the absence of an active proteinase, the scaffolding proteins remain associated with the protein shell, preventing packaging of the viral DNA, and the procapsid is unable to mature.¹⁴⁴

Unlike adenoviruses, which accumulate in the nucleus and are released on lysis of the cell, herpesviruses exit the nucleus by budding into the lumen of the nuclear membrane. This process depends on the products of two highly conserved genes—UL31 and UL34—that encode a phosphoprotein and

a type II membrane protein, respectively. Nuclear localization of pUL31 depends on its interaction with pUL34.⁹⁷ Although both proteins are present in the primary enveloped virions present in the lumen of the nuclear membrane, they are absent from mature virions, consistent with a model in which herpesvirus virions are first enveloped at the inner nuclear membrane, de-envelop by budding through the outer nuclear membrane and are re-enveloped by Golgi membranes in the cytoplasm. The complexities of this interaction and subsequent steps in assembly will be discussed later in this chapter.

For influenza virus to take advantage of its unusual capacity to “steal” the capped 5′ ends of host cell mRNAs to initiate its own mRNA synthesis, transcription and viral RNA replication must occur in the nucleus (Chapters 5, 40 and 41). Genomic (minus sense) RNAs are replicated by a different mechanism to yield templates for mRNA synthesis as well as progeny viral genomes. The eight viral RNA segments of this virus are packaged into individual RNPs containing the four proteins of the transcriptase complex (PB1, PB2, PA, and NP; each containing a functional NLS sequence) and the nuclear export protein (NEP; previously NS2), but are not exported into the cytosol until late in infection when the viral matrix protein begins to be synthesized.¹¹³ Under conditions where matrix synthesis is inhibited, the viral ribonucleoproteins (vRNPs) accumulate in the nucleus, tightly associated with the nuclear matrix. The block to export can be relieved by expression of matrix from an independent vector.²² It has also been shown that the vRNPs remain in the nucleus of cells if NEP is not encoded by the virus. NEP does not interact directly with vRNPs; rather, it mediates (RanGTP-dependent) formation of a bridge between the cellular export receptor Crm1 and the N-terminal domain of M1, which in turn binds to the vRNP via its C-terminal domain. This *daisy-chain* complex of (Crm1–RanGTP)–NEP–M1–vRNP is likely what mediates the export of vRNP across the nuclear envelope.^{2,137} Matrix association with the vRNPs also appears to be important for preventing their re-entry into the nucleus, because conditions such as acidification or mutations that promote dissociation of M1 allow the RNPs to be reimported.²²⁸ Thus, the matrix protein of influenza virus is a key modulator of vRNP transport into and out of the nucleus.

Assembly of Viruses in the Cytoplasm

Targeting and import of proteins into the nucleus or secretory pathway involves well-characterized motifs on the proteins involved; therefore, the processes by which proteins are targeted to destinations within the cytoplasm remains for the most part obscure. Nevertheless, most viruses, even those that are nonenveloped, initiate or complete their assembly in association with membranes of the secretory or endocytic pathways, although the intracellular pathways that function to transport their capsid components and genomes to these sites have not been defined. Reoviruses are the only animal viruses that appear to complete their assembly entirely in the cytoplasm without the involvement of membranes. Genome replication and virus assembly both occur in specialized areas of the cytoplasm known as virus factories or viroplasm. The virus nonstructural proteins NSP2 and NSP5 appear to play a critical role in establishing these sites of virus replication and can form morphologically similar structures when expressed in the absence of other viral proteins.¹⁵⁸ It is likely that they are responsible for recruitment of the other viral proteins and viral

nucleic acid to these sites, thereby avoiding the complexities of transporting virion components to multiple separate cytoplasmic assembly sites following translation.

Intracytoplasmic Transport and Assembly of Retroviral Capsids

Retroviruses are enveloped viruses that, for the most part, complete their assembly by budding through the plasma membrane of the infected cell. For these viruses, the immature capsid of the virus is assembled from polyprotein precursors that must be transported through the cytoplasm to the inner leaflet of the membrane. The viral glycoproteins, on the other hand, must be transported through the secretory pathway of the cell to the cell surface, where they co-localize with the nascent,

membrane-extruding capsid (Fig. 6.7). All replication competent retroviruses contain four genes that encode the structural and enzymatic components of the virion. These are *gag* (capsid protein), *pro* (aspartyl proteinase), *pol* (reverse transcriptase and integrase enzymes) and *env* (envelope glycoprotein) (Chapter 47). However, the product of the *gag* gene has been shown to possess the necessary structural information to mediate intracellular transport, to direct self-assembly into the capsid shell, and to catalyze the process of membrane extrusion known as budding.¹⁸³ For most retroviruses, the nascent Gag polyproteins are transported to the plasma membrane, where assembly of the capsid shell and envelopment occur simultaneously (see Fig. 6.7, Pathway 1). Viruses that undergo this *type C* form of morphogenesis include members of the alpha- and

FIGURE 6.7. Assembly of retroviruses. The assembly pathways of retroviruses that exhibit C type morphogenesis (*Pathway 1*), B-/D-type morphogenesis (*Pathway 2*), and that of the foamy viruses (*Pathway 3*) are shown. The envelope glycoproteins are translated on membrane-bound polysomes and, for most retroviruses, are transported to the cell surface through the cell's secretory pathway (*Pathway 4*). For all morphogenic classes, the Gag proteins are synthesized on free polysomes. In the case of the C-type morphogenic viruses (i.e., RSV and HIV), the Gag and Gag-Pol proteins migrate either individually or in small multimers to the plasma membrane, where immature capsid assembly and envelopment occurs concurrently (1a). At some point in this pathway, the viral genomic RNAs associate with the Gag and Gag-Pol precursors and are incorporated into the developing capsid. For HIV in macrophages, assembly can occur on deep invaginations of the plasma membrane to which Env has been targeted (1d). In the case of the B-/D-type viruses, polysomes translating Gag and Gag-Pol precursors are first transported via microtubules to an intracytoplasmic, pericentriolar assembly site (2a), where they assemble into immature capsids. The immature structures are then transported, most likely in association with endosomal vesicles (2b), to the plasma membrane (2c), where they associate with the envelope glycoproteins and induce viral budding. For both classes of retroviruses, the capsids of the nascent immature particles appear as doughnut-shaped structures and contain unprocessed Gag and Gag-Pol precursors (1b and 2d). The mature virus particles contain electron-dense cores with morphologies characteristic of the virus (1c and 2e). The maturation step is required for infectivity and is the result of the activation of the viral protease, which cleaves the Gag and Gag-Pol precursors into the internal structural and enzymatic proteins of the virus. For the foamy viruses, Gag and Pro-Pol precursors also assemble into immature capsids in a pericentriolar site (3a); however, budding primarily occurs at the ERGIC compartment, where the viral glycoproteins are retained (3b). The enveloped virion is presumably transported to the plasma membrane by transport vesicles (3d). Maturation cleavage of the immature core is limited to removal of 4kd from the C-terminus of the precursor; the mature infectious virion maintains an immature morphology (3e). RSV, Rous sarcoma virus; HIV, human immunodeficiency virus; ERGIC, endoplasmic reticulum–Golgi intermediate compartment.

gammaretroviruses. Lentiviruses and deltaretroviruses assemble their capsids in a similar fashion in most cell types. In the second morphogenic class of retroviruses, the *type B/D* class, the Gag precursors are targeted first to an intracytoplasmic site, where capsid assembly occurs. These assembled immature capsids are then transported to the plasma membrane, where they undergo budding and envelopment (see Fig. 6.7, Pathway 2). Viruses that undergo this process of assembly and release include members of the betaretroviruses. Members of the spumavirus family also assemble immature capsids in the cytoplasm but are targeted to the ER or ERGIC for envelopment (see Fig. 6.7, Pathway 3).

Whereas the size and protein content of the precursor varies between different retroviral families, at least three *gag*-encoded proteins are found in all retroviruses: the matrix protein (MA), the capsid protein (CA), and the nucleocapsid protein (NC). In addition to these functionally conserved domains, the Gag precursor can, depending on the virus encoding it, contain additional peptide sequences (Fig. 6.8) whose functions in virus assembly and future cycles of infection are only now being resolved.

The detailed mechanisms by which the capsid precursor proteins are directed to the site of assembly are only now starting to be elucidated in molecular detail; however, the process is mediated primarily by the MA domain of the Gag precursor. In most retroviruses, the matrix protein contains two elements involved in plasma membrane targeting. The first of these is

FIGURE 6.8. Organization of the retroviral Gag precursor. The Gag precursor polyproteins of all retroviruses contain, beginning at the N-terminus, matrix (MA), capsid (CA), and nucleocapsid (NC) domains linked in this order. The *gag* gene products of the betaretrovirus Mason-Pfizer monkey virus (M-PMV), the alpharetrovirus Rous sarcoma virus (RSV), the gammaretrovirus murine leukemia virus (MuLV), and the lentivirus human immunodeficiency virus (HIV) are shown. The unshaded boxes represent regions of the Gag precursor for which no common functions or locations in the mature virion have been established. However, for the three representatives of the alpha-, beta-, and gammaretroviruses, a *late domain* function required for pinching off of the virus particle from the cell is located between the MA and CA domains. The specific name associated with the Gag cleavage products is derived from their respective apparent molecular weights ($\times 10^{-3}$).

an N-terminal myristic acid, which is thought to insert into the hydrophobic lipid bilayer. The second is a surface patch of basic amino acids that are hypothesized to mediate the initial interaction of Gag with the negatively charged, phospholipid head groups of the membrane. Mutations that interfere with either myristoylation or the charged residues can abrogate plasma membrane targeting, and in some instances, the mutated Gag precursors are targeted to internal membranes.⁵⁷

In the betaretroviruses, where capsid assembly and virus budding are discrete events, a genetic dissection of this process has shown that Gag-containing precursors express a dominant sorting signal (the cytoplasmic targeting/retention signal [CTRS]) that targets the proteins to the initial assembly site.²⁸ Recent studies suggest that the CTRS interacts with Tctex-1, a light chain of the microtubule-associated dynein motor, and directs nascent Gag proteins and translating polysomes to the centriolar region of the cell, where capsid assembly occurs.^{194,222} A point mutation within the Mason-Pfizer monkey virus (M-PMV) CTRS domain can abrogate intracytoplasmic targeting and results in the type C-like transport of precursors to the plasma membrane, where efficient capsid assembly occurs.⁸¹ Efficient transport of wild-type capsids out of the assembly site depends on both the presence of the M-PMV Env protein and endosomal trafficking, and appears to reflect a requirement for Gag-Env interactions at the pericentriolar recycling endosome.¹⁹³ Interestingly, studies in murine leukemia virus (MuLV), in which the viral RNA was tagged for visualization by fluorescence microscopy, have suggested that prebudding complexes of Env, Gag, and RNA associate with late endosomes and are routed in this way to the plasma membrane.⁸ It is likely that similar preassembly complexes also participate in the intracellular transport of HIV-1 Gag proteins, because their transport is modulated by the cellular adaptins AP-1, AP-2, and AP-3, and intracellular interactions with Env direct Gag assembly to specific plasma membrane regions of the cell.^{5,49} Although in macrophages HIV-1 Gag was initially thought to be targeted to a late endosomal compartment for intracellular assembly and budding, more recent studies suggest that these compartments are derived from deep invaginations of the plasma membrane^{5,11} (see Fig. 6.7, Pathway 1d). Targeting of the plasma membrane by HIV-1 Gag for assembly in part reflects specific MA domain recognition of phosphatidylinositol 4,5-bisphosphate [PI(4,5)P₂], which is enriched there. Depletion of this lipid component by overexpression of the cognate phosphatase (5-phosphatase IV) redirects HIV-1 assembly away from the plasma membrane to internal membranes.⁵

Irrespective of the assembly site, Gag precursor proteins must associate in a reproducible fashion to assemble into the nascent capsid. Mutational analyses of *gag* genes, as well as *in vitro* assembly studies, have shown that the CA and NC domains of Gag play a critical role in assembly; MA is dispensable for this process.^{36,57} NC binding to RNA may act to nucleate the capsid assembly process, whereas CA forms a symmetrical hexameric network of proteins. *In vitro*, the CA protein alone can assemble into tubes that exhibit local sixfold symmetry (hexamers), and cryo-electron tomography studies of immature HIV-1 capsids have revealed a similar but distinct arrangement of the CA domain of Gag. A striking observation in the context of HIV-1 is that released immature virus particles have an incomplete protein shell, with the ordered

Gag lattice covering, on average, only two-thirds of the membrane surface.^{19,231}

For most retroviruses, capsid assembly drives the process of membrane extrusion known as budding. As we will discuss later, for an infectious virus to be formed, the Gag precursors (or for other viruses, NPs) and surface glycoproteins of the virus must be targeted to the same region of the same membrane. In this way, during virus budding, a proper complement of glycoproteins can be incorporated into the nascent virion.

Assembly of Enveloped Viruses at Cellular Membranes

For most enveloped viruses, the location within the cell at which envelopment takes place is determined by the targeting to or retention of the viral glycoproteins at that site. Indeed, with the exception of the retroviruses, the efficiency of virus budding and particle release highly depends on the presence of the envelope glycoprotein(s), and in its absence, few particles are produced. Because the glycoproteins define the site of virus budding, specific interactions between the viral NP and the glycoproteins, sometimes mediated by a matrix protein, must take place to ensure that the genome of the virus is incorporated. For each of the viruses that assemble at intermediate points within the secretory pathway, fully assembled viruses must traverse the remainder of the pathway to be released from

the cell (Fig. 6.9). Glycoproteins on these released viruses have complex oligosaccharides and are most likely modified by the Golgi-localized enzymes on the way to the cell surface.

Assembly at the Endoplasmic Reticulum–Golgi Intermediate Compartment

The coronaviruses are positive-stranded RNA viruses with large (30-kb) genomes packaged in a helical nucleocapsid. The nucleocapsid acquires its envelope by budding into the lumen of the ERGIC, a pre-Golgi compartment of the secretory pathway. Coronaviruses invariably encode three envelope proteins. The spike protein (S), which determines the host range of the virus, is a type I glycoprotein that forms the distinct bulbous peplomers of the virus. Expressed independently of the other glycoproteins, infectious bronchitis virus (IBV) S is transported to the plasma membrane, although it does contain both ER retention and endocytosis signals that can redirect it to the ERGIC.¹⁰⁶ The most abundant virion protein is the membrane (M) glycoprotein. M spans the lipid bilayer three times, exposing a short N-terminal domain outside the virus and a long C-terminus inside the virion. Because of its abundance and because M is transported to the Golgi complex but not to the surface, it was initially thought to define the site at which this family of viruses was enveloped. Studies, however, have shown that the small envelope protein (E), which is only

FIGURE 6.9. Viral assembly at cellular membranes. Schematic representation shows the intracellular locations at which enveloped virus assembly takes place. For each virus that is enveloped at organelles within the secretory pathway, the virions must traverse the remainder of the pathway to be released from the cell. Rotaviruses appear to utilize the ER membrane as a scaffold for assembly of virion proteins—the capsids that form during the assembly process are only transiently enveloped, and nonenveloped particles accumulate in the lumen of the ER. Coronaviruses localize the three membrane proteins (E, M, and S) in the ER–Golgi intermediate compartment, and virus budding occurs into the lumen of this compartment of the secretory pathway. In contrast, the vaccinia virus nucleocapsid appears to be wrapped by a double membrane derived from this compartment [Poxvirus (1)] but remains free in the cytoplasm so that it can then be further enveloped by Golgi-derived membranes [Poxvirus (2)]. Similarly, herpesviruses initially bud into the lumen of the nuclear membrane [Herpesvirus (1)]; however, after fusion and release of the capsid into the cytoplasm, it is re-enveloped by Golgi membranes [Herpesvirus (2)]. The G1 and G2 glycoproteins of bunyaviruses co-localize in the trans-Golgi compartment to direct budding of nucleocapsids at this location. For the retroviruses, which can assemble and release virus particles in the absence of envelope glycoproteins, the envelope glycoproteins appear to direct virus budding to the basolateral plasma membrane of polarized epithelial cells. ER, endoplasmic reticulum.

a minor component of virions, is the key to defining the site and nature of coronavirus envelopment.⁷⁷ E is a hydrophobic type I membrane protein that localizes to the ERGIC and induces the formation of tubular, convoluted membrane structures characteristic of virus infection.^{34,166} The E protein of IBV appears to be retained in the ERGIC by a novel ER retrieval signal (RDKLYS-COOH) and localizes M to this site through intermolecular interactions.¹⁰² Co-expression of E, M, and S results in the assembly and release from cells of virus-like particles (VLPs) containing these three viral membrane proteins. The enveloped particles produced by this system form a homogeneous population of spherical particles indistinguishable from authentic virions in size and shape.²²¹ Only M and E are required for efficient particle formation, and expression of E alone can mediate particle release.¹¹⁰ The S glycoprotein is thus dispensable for virus particle assembly but is retained in the Golgi by the M protein, which appears to direct its assembly into virions. M protein also directs the incorporation of nucleocapsids containing the genome-length RNA into virions, and nucleocapsids associated with newly synthesized M protein have been localized to the budding site in the ERGIC.¹³⁵

Although most retroviruses are enveloped at the plasma membrane of the cell, for most members of the spumavirus genus, this occurs on internal membranes. In human fibrosarcoma cells, primate foamy virus (FV) Gag and Env appear to co-localize predominantly in the trans-Golgi region of the cell;²³⁵ however, in other cells, immature capsids appear to bud into the ERGIC region of the secretory pathway. This is consistent with the observation that expression of the primate FV Env complex, gp80/gp48, in the absence of other structural proteins, results in its localization to the ER. A di-lysine ER retrieval motif at the C-terminus of gp48 is responsible for this localization, and mutation of either lysine results in efficient transport of the protein to the plasma membrane. Although a greater fraction of capsids bud from the plasma membrane in mutant virus-infected cells, envelopment of capsids at the ER is still observed.⁶⁶ A second distinguishing feature of foamy viruses is the dependence of capsid envelopment on Env expression.⁶ As with the betaretroviruses, assembly of immature FV capsids is targeted to the pericentriolar region of the cell by a CTRS located around an arginine residue at position 50 in Gag.²³⁵ They are then transported to the ER (or plasma membrane) for envelopment. In the absence of FV Env, these preassembled capsids do not associate with membranes or initiate budding. Recent experiments have shown that it is the posttranslationally cleaved (148 amino acids long), membrane-spanning, signal peptide domain of the FV Env that mediates capsid membrane association/envelopment; they have also shown that this protein is incorporated into the virus in the process.¹⁰³

Assembly in the Golgi Complex

Bunyaviruses are negative-stranded, enveloped viruses with a segmented genome that assembles in tube-like virus factories that are built around the Golgi complex and are connected to mitochondria and rough ER²²⁶ (see Fig. 6.9). By physically juxtaposing viral RNA replication and assembly, these factories appear to allow accumulation of RNPs that can associate with viral glycoproteins and bud into the lumen of swollen Golgi stacks. The glycoprotein spikes of the best-characterized member of this family, Uukuniemi virus, are comprised of

two type I glycoproteins—Gn (previously G1) and Gc (G2)—that determine the site of virus budding. Gn and Gc are cotranslationally cleaved from a single precursor protein by signal peptidase, which cleaves after the internal signal sequence that mediates translocation of Gc. The two proteins have been shown to fold with distinctly different kinetics, but once properly folded, they form a Gn-Gc heterodimer that is transported to the Golgi complex. Gc expressed in the absence of Gn is retained in the ER, whereas Gn expressed alone is targeted to the Golgi.⁷¹ The Uukuniemi virus Golgi localization signal of Gn has been mapped, through analysis of mutations and glycoprotein chimeras, to the membrane proximal half of the 98 amino acid long cytoplasmic tail of the protein. Glycoprotein retention in this case appears, therefore, to depend on interactions between the cytoplasmic tail of Gn in the Gn-Gc heterodimer with components residing on the cytoplasmic side of the Golgi membrane. However, although all bunyavirus Gn-Gc complexes accumulate in the Golgi, the exact location and nature of the signal(s) that ensure this do appear to differ among the genera.²²⁶

During assembly of bunyaviruses, the helical nucleoproteins, consisting of the three single-stranded genomic RNA segments and the associated nucleocapsid (N) protein, accumulate in the Golgi component of the virus factories and through interactions with the Gn and Gc cytoplasmic domains initiate the budding of virus particles into the Golgi lumen. The region of the secretory pathway at which Gn-Gc heterodimers accumulate clearly defines the budding site, because in the presence of brefeldin, a drug that redistributes Golgi components to the ER, virus budding occurs into the ER.⁷¹

Assembly at the Plasma Membrane

Members of several virus families undergo their envelopment at the plasma membrane. These families include the togaviruses, the rhabdoviruses, the para- and orthomyxoviruses, and the retroviruses. In each of these cases, the viral glycoproteins, either as hetero-oligomeric complexes or homo-oligomers, have traversed the entire secretory pathway to be delivered to the plasma membrane of the cell. Assembly at the plasma membrane obviates the need for the assembled virus to navigate additional compartments of the secretory pathway, because virions are released directly into the external milieu of the cell. Alphaviruses are among the best characterized of these different viral systems, because a combination of biochemical, genetic, and structural information has been amassed to shed light on the complexity of this assembly process. The major glycoproteins E1 and E2 of the alphaviruses are translated from a subgenomic 26S RNA as a pE2, 6K, E1 precursor complex. The 6K and E1 proteins are released from the precursor by signal peptidase but remain in a complex with pE2. Following transport to the Golgi, pE2 is processed to E2 and E3. Stable trimers of E1-E2 heterodimers are then transported to the plasma membrane, where they associate with nucleocapsids formed from the capsid (C) protein and genome-length RNA. The 6K protein travels to the plasma membrane with the E1-E2 complex but is inefficiently incorporated into virions.^{62,89} Cryo-electron microscopy analyses of mature alphavirus particles have revealed a detailed structure of this enveloped virion (Chapters 3 and 23). These studies have shown that both the envelope and the core display icosahedral symmetry. Surprisingly, however, the trimers of E1 and E2 are located at the

threefold and quasi-threefold symmetry axes of the pentameric and hexameric order of the nucleocapsid. Moreover, the heterodimers of each spike splay out above the membrane in a skirt-like fashion, traverse the lipid bilayer individually, and interact with three underlying capsid (C) proteins that belong to three separate capsomeres. This creates a complex network of molecular interactions where the glycoprotein–capsid protein interactions mediate not only the binding of the nucleocapsid to the spikes but also stabilize the connections between the capsomeres.⁸⁹ Above the membrane, the skirts formed by the E1-E2 heterodimers form lateral connections that mimic the pentameric and hexameric arrangement of the capsid. These interactions may facilitate the process of budding by providing a multivalent binding site for the capsid, as well as by providing a force for membrane bending. Budding, however, requires a cooperative interaction between the glycoproteins and the capsid protein, because in the absence of either, budding does not occur. Moreover, mutations in the cytoplasmic tail of the E2 protein alone can abrogate budding. Two models have been proposed for assembly.⁶² In the first, glycoprotein trimers assemble around a preformed nucleocapsid that is associated with the inner leaflet of the plasma membrane. The second hypothesizes that it is through interactions between E1-E2 heterotrimers that the icosahedral structure of the virus is established and that interactions between the E1-E2 heterodimers and C proteins organize the nucleocapsid similarly. Evidence for the latter model came from deletion mutants in C that are defective in the formation of intracellular capsids but that nevertheless can associate with E1-E2 to facilitate the release of $T = 4$ icosahedral capsids.⁵⁶

For the negative-strand RNA viruses, orthomyxoviruses, paramyxoviruses, and rhabdoviruses, an additional protein, the matrix protein, mediates the interactions between the viral glycoproteins and the RNP and appears to play a key role in envelopment. These proteins are able to bind to membranes through hydrophobic domains or, as with the retroviruses, through a cluster of positively charged residues that initiate electrostatic interactions with the plasma membrane. Cross-linking studies have demonstrated that these M proteins form homo-oligomers in the virus and can self-associate *in vitro* or when expressed at high levels in cells. As discussed earlier, the M1 protein of influenza virus acts to mediate the transport of RNPs from the nucleus to the site of virus assembly on the plasma membrane, and it seems likely that the intracytoplasmic transport pathway for this M1-vRNP complex involves interactions with cytoskeletal components of the cell.⁴ The importance of the M protein in the paramyxovirus budding process was inferred from the defective measles viruses found in subacute sclerosing pan-encephalitis that are unable to assemble virus particles and that have mutations in the M protein coding region.¹³ However, the development of reverse genetics systems for the negative-stranded viruses, in which mutations can be reintroduced into the viral genome, has allowed a more rational approach to examining these questions. Construction of rhabdovirus genomes that lack the M coding region resulted in a dramatic (more than 10^7 -fold) decrease in the release of virus particles, and those that were released lacked the characteristic bullet-shape morphology. The defect could be complemented by expression of M *in trans*.¹²⁰ Thus, in the rhabdoviruses, the M protein condenses the helical RNP into its characteristic shape and mediates the envelopment process. Similarly, for the orthomyxoviruses, M1 can define

whether spherical or filamentous forms of the virus particle are produced¹⁷; although in the absence of M1 particles can be released, this is a much less efficient process.¹⁷⁸

Reverse genetics approaches have also shed light on the role of the G glycoprotein in rhabdovirus assembly and of the HA and NA in orthomyxovirus assembly. Rhabdoviruses that lack the G-protein coding domain do assemble and release bullet-shaped particles but at only 3% to 10% the efficiency of wild-type.^{119,173} Initial studies with G proteins lacking a cytoplasmic tail have suggested that this domain might be important in the budding process; however, more recent studies have shown that although there is a general requirement for a short cytoplasmic tail, it is amino acid sequence independent, and that G proteins with large C-terminal extensions can be efficiently incorporated into virions, thereby leaving the basis for M protein interactions with G unresolved.⁸⁸ Although foreign glycoproteins can be efficiently incorporated into rhabdovirus particles (creating pseudotype particles), they do not stimulate budding.¹⁷¹ This is consistent with experiments that have identified a domain within the extracellular membrane-proximal stem (GS) of vesicular stomatitis virus (VSV) G that is required for efficient VSV budding. Recombinant viruses encoding glycoprotein chimeras with 12 or more membrane-proximal residues of the GS, as well as the G protein transmembrane and cytoplasmic tail domains, produced near-wild-type levels of particles. In contrast, those with shorter regions produced 10- to 20-fold fewer particles. It is possible, therefore, that this region of the G protein membrane-proximal domain modifies the membrane to facilitate the budding process.¹⁷³ Recent cryo-electron microscopy studies of VSV suggest that assembly begins with the formation of an RNA-N protein nucleocapsid ribbon, which, after forming a tight ring that represents the tip of the bullet-shaped particle, is forced to curl into larger rings that eventually tile the helical trunk. The assembling structure would be stabilized by the binding of M protein to the outside of the nucleocapsid, which in turn forms a triangular platform for binding G-trimers and the lipid membrane.⁶⁴

In influenza virus, the fact that the cytoplasmic domains of all three membrane proteins (HA, NA, and M2) are highly conserved in all isolates of the virus pointed to a role for these domains in assembly of enveloped virus. Early studies indicated that HA proteins with foreign cytoplasmic tails are not incorporated into virions, although HAs lacking this domain can be incorporated at levels 50% that of wild-type.¹³³ Studies using reverse genetics have confirmed these findings and have shown that the short (six amino acid) cytoplasmic domain of NA also plays an important role in morphogenesis. Viruses encoding the truncated NA protein were released less efficiently and were larger and more filamentous. However, in viruses encoding tailless versions of both HA and NA, a 10-fold reduction in virus release was observed and morphogenesis was drastically altered. Virus particles released from these cells were greatly elongated with an extended irregular shape and a reduced level of viral RNA. Similarly, truncation of the cytoplasmic tail of M2, which binds to M1, results in much reduced virus infectivity, coupled with reduction in the amount of packaged RNA and budding efficiency.¹¹⁸ Thus, it appears that for influenza virus, the interactions between M1 and the viral membrane-spanning proteins are so important for envelopment and morphogenesis that the virus has developed redundant interaction domains in these proteins.^{136,178}

With the exception of the spumaviruses, glycoprotein–capsid interactions are not absolutely required for the assembly and release of enveloped retrovirus particles; the Gag precursor alone contains the information necessary to be specifically targeted to the plasma membrane and to drive budding. Nevertheless, for members of the lentivirus family, such as HIV and simian immunodeficiency virus (SIV), that encode envelope glycoproteins with a long (150+ amino acid) cytoplasmic domain, a specific interaction between this region of the transmembrane component of Env and the MA domain of the Gag precursor appears to be necessary for Env incorporation. For these viruses, mutations in MA or in the cytoplasmic tail can abrogate Env incorporation.²⁶ Whereas viral glycoproteins are not required for assembly and budding of most retroviruses, in the case of M-PMV, Env appears to facilitate the intracellular transport of Gag molecules to the plasma membrane.¹⁹³ An understanding of the process by which Gag is transported to the plasma membrane remains incomplete; however, there is a growing body of evidence that Gag and Env may interact at intracellular sites and utilize components of the endocytic pathway to target these structural gene products, as well as genomic RNA, to an assembly site on the plasma membrane. Further evidence for an Env–Gag interaction is derived from polarized epithelial cells, where retroviral glycoproteins define the plasma membrane domain at which virus budding and release occur (see later discussion).

Several viruses appear to make use of cholesterol- and sphingolipid-rich domains on the plasma membrane known as lipid rafts to assist in the concentration and organization of viral components for assembly.²⁵ These rafts are characterized by their insolubility in detergent at low temperatures (4°C), and proteins associated with them remain in the insoluble fraction following extraction from cells. Both HA and NA of influenza virus cluster in lipid rafts via targeting signals that have been mapped to both their transmembrane and cytoplasmic domains, and it is hypothesized that through interactions with the clustered glycoproteins, M1 and the vRNPs are organized for budding.¹³⁷ Consistent with these observations, the lipid bilayer of influenza virions is enriched in cholesterol and sphingolipids and appears also to be in ordered domains.¹⁸⁹ Similarly, the glycoproteins and capsid precursors of HIV-1 have been shown to associate with lipid rafts, and depletion of cholesterol from the plasma membrane impairs HIV-1 particle production.²²⁵ Gag–Env interactions appear to be required for Env association with lipid rafts, as mutations in either MA or the cytoplasmic domain of the gp41 transmembrane protein that interfere with Gag–gp41 interactions prevent Env association with rafts.¹⁰ Although it was initially assumed that VSV assembled independently of rafts, it has been shown that G clusters in microdomains and can co-localize on the plasma membrane with proteins known to be located in rafts.¹⁶³ Thus, it is possible that VSV also utilizes rafts to organize its components for assembly.

Targeting of Viral Glycoproteins in Polarized Epithelial Cells Defines the Site of Budding

Many viruses initiate their infection of a host by interacting with cells at an epithelial surface. Individual cells within an epithelial layer are tightly connected by junction complexes that form a barrier to diffusion of molecules throughout the cell membrane and divide the cell surface into two distinct plasma membrane domains: the apical domain, which faces the exterior,

and the basolateral domain, which faces the interior. As a result of differential targeting of lipids and protein components to apical and basolateral membranes, epithelial cells in tight monolayers are highly polarized with each plasma membrane domain having a distinct lipid and protein composition.¹⁷⁵ The assembly and release of many viruses from epithelial cells is also highly polarized, occurring selectively at either the apical or basolateral surface. Influenza virus releases newly assembled virions from the apical surface of polarized epithelial cells, whereas VSV and many retroviruses are released from the basolateral membrane. In the absence of other viral proteins, VSV G protein and several retroviral Env proteins are transported to the basolateral surface, whereas HA, NA, and M2 are targeted to the apical membrane.^{32,136} Sorting of proteins to one or the other domain occurs in the trans-Golgi network, and recent evidence suggests that proteins destined for the basolateral surface contain within their cytoplasmic domain motifs that direct the protein to that membrane. In the VSV G protein, a tyrosine-based motif within the cytoplasmic tail appears to be critical for basolateral targeting.²¹⁴ Similarly, tyrosine-based endocytosis motifs in the cytoplasmic domain of both the MuLV and HIV Env proteins are important for their polarized expression and for basolateral budding of their cognate viruses.

Apical transmembrane proteins appear to contain two signals that probably act cooperatively in targeting to the apical surface. Glycosylation in the ectodomain and a signal in the membrane-spanning domain function together to ensure association with sphingolipid-cholesterol-enriched membrane domains or rafts, which have been proposed to mediate apical transport in polarized epithelial cells.

In the absence of a basolateral targeting signal, retroviral Env proteins are delivered to and virus buds from both membranes with equal efficiency, arguing that interactions with Env guide Gag to the basolateral surface.¹⁰⁵ The rhabdoviruses differ in this regard, in that even when the basolateral targeting signal for G has been mutated such that G is transported to the apical surface, virus assembly still occurs predominantly at the basolateral surface. Similarly, under conditions where the influenza virus HA is directed to the basolateral surface, virus budding remains predominantly apical. In these viruses, therefore, it appears that the internal components of the virion possess independent targeting signals that direct them to their respective membranes.¹³⁶ Polarized virus assembly and release may be important in determining the pathogenesis of viral infections, as it can influence, in a major fashion, the pattern of virus spread in the infected host.³²

Complex Interactions with the Secretory Pathway

Whereas most enveloped viruses undergo assembly and envelopment at a single site within the secretory pathway, some viruses have a more complex interaction that can involve de-envelopment or re-envelopment as part of their assembly pathway.

Rotavirus Assembly Within the Endoplasmic Reticulum

Rotaviruses are nonenveloped viruses that undergo transient envelopment at the ER as an essential step in the formation of the mature double-shelled (triple-layered) virus that is retained within the lumen of the ER until cell lysis. As with the reoviruses, the nucleocapsid, in this case containing

11 double-stranded RNA segments, is assembled in electron-dense areas of the cytoplasm, located close to the ER membrane, known as viroplasm. This assembly domain depends on expression of two nonstructural proteins—NS2 and NS5—and mutations or silencing of either gene product results in its abrogation.^{55,107,159} The nucleocapsids that assemble have an outer icosahedral shell assembled from VP6, the most abundant protein of the virus, surrounding an inner core (Chapters 44 and 45). They appear to bud directly into regions of the ER that contain the two outer shell proteins VP7 and VP4. A nonstructural protein, NSP4, which forms hetero-oligomers with the two outer shell proteins, mediates the interaction of the immature particle with the ER membrane.^{125,147,212}

The exact topology of VP7 in the ER is not known. The mature protein has a cleaved signal peptide but is retained in the ER as if it were an integral membrane protein.^{94,200} VP4 is thought to associate with VP7 and NSP4 just prior to budding of the nucleocapsid into the ER. Enveloped particles can be observed in the lumen of the ER, which then undergo a process of calcium-dependent de-envelopment, forming in the process an outer icosahedral shell of VP7 and VP4.¹⁶⁵ This process seems to be directed by VP7 because the silencing of this protein has not blocked the budding of double-layered particles into the ER but instead has arrested maturation at the membrane-enveloped particle stage in this compartment.¹⁸² The rapid association of VP4 with lipid rafts and the nonlytic release of rotaviruses from the apical plasma membrane of gut epithelial cells has led to the suggestion that the site of budding might be the ERGIC and that rafts may play a role in transport of virus directly from this region to the plasma membrane.^{37,47} Thus, this nonenveloped icosahedral virus appears to transiently utilize membranes of the secretory pathway as a scaffold on which to assemble an icosahedral shell and a nontraditional vesicle-mediated route to the plasma membrane.

Herpesvirus Transport from the Nucleus

As we described previously, the end product of herpesvirus capsid assembly is a large icosahedral structure that is too large to transit the nuclear pore. Members of this family have therefore evolved to utilize a complex envelopment/de-envelopment/re-envelopment strategy that allows the final acquisition of a lipid envelope to occur at a late compartment of the secretory pathway¹²¹ (Fig. 6.10). The first evidence for this initially controversial pathway came from electron microscopic observations of infected cells.^{71,169} Capsids that have assembled in the nucleus

acquire an envelope derived from the inner leaflet of the nuclear membrane as they bud into the luminal space (termed *primary envelopment*). Products of the UL31 and UL34 genes are involved in this process—the former encoding a nuclear phosphoprotein and the latter encoding a type II membrane protein. Both proteins are located on the nuclear membrane; however, the UL31 protein requires UL34 for nuclear targeting. Absence of either protein abrogates primary envelopment and results in capsid accumulation in the nucleus.¹⁶⁷ Although these proteins are components of the primary enveloped virions, they are absent from mature virions. Primary envelopment does not occur in the absence of the pUL25 capsid-associated protein and thus appears to be required for the budding process.⁹⁷ The initially enveloped virions lack proteins that are abundant in mature virus particles (e.g., pUL47 or pUL49), indicating that the most prominent components of the viral tegument have to be added during later steps of virion morphogenesis.¹²³

In the de-envelopment step, the newly enveloped virus fuses with the outer nuclear membrane to release the capsid into the cytoplasm. It is here that tegument proteins of the mature virus, a collection of proteins including transcription factors located between the viral capsid and its lipid bilayer in the mature particle, are proposed to associate with the capsid prior to its re-envelopment by Golgi-derived membrane vesicles.¹²³ For herpes simplex virus and pseudorabies virus, glycoproteins of the gE/I complex together with gM appear to be essential for the re-envelopment step, and in their absence, intracytoplasmic aggregates of tegument-associated capsids are formed.¹⁸

Some of the clearest evidence for this complex assembly pathway comes from studies of human cytomegalovirus (HCMV) and human herpesvirus 6 (HHV-6). In these viruses, the tegument is a dense structure that can be observed in electron micrographs. Enveloped virions in the lumen of the nuclear membrane display no evidence of tegument but acquire this layer following loss of the nuclear-derived envelope and subsequent release into the cytoplasm.^{176,216} Studies of the glycoproteins of the gamma herpesvirus, Epstein-Barr virus, also support this model. Distribution of the viral glycoproteins gp110 and gp350/220 is consistent with the former being incorporated in virions at the nuclear membrane and then lost on budding into the cytoplasm, whereas the latter is acquired only during re-envelopment in the Golgi.⁶⁷ Similarly, studies of the lipid composition of extracellular HSV-1 virions indicate that it is similar to that of the Golgi complex and distinct from that of the nucleus.²²⁰ Why would viruses evolve to utilize such

FIGURE 6.10. Herpesvirus assembly. In the re-envelopment pathway, nascent assembled capsids bud into the lumen of the nuclear membrane utilizing a subset of virally encoded glycoproteins. These enveloped particles then fuse with and are released from the outer nuclear membrane into the cytoplasm. There they associate with the tegument proteins and are transported through the cytoplasm to be enveloped by Golgi-derived membranes that contain the full complement of virion glycoproteins.

a complex assembly strategy? Perhaps the most persuasive argument comes from the perspective of the neurotropic alphaherpesviruses. These viruses infect nerve endings in the periphery; however, DNA replication and capsid assembly must occur in the cell body. To initiate a second round of infection at the nerve synapse, viral components must be transported down the axon. Thus, by separately transporting the viral capsids on microtubules and viral glycoproteins by the vesicular pathway, the site at which infectious virus is assembled can be much more accurately controlled.^{120,215}

Poxvirus Acquisition of Multiple Membranes

Poxviruses, exemplified by vaccinia virus, exhibit an equally complex interaction with the secretory pathway. These large DNA viruses, which encode all of the machinery necessary for genomic replication and transcription, propagate entirely in the cytoplasm in specialized areas designated as virus factories (Chapters 66 and 67). The assembly and envelopment of these viruses is particularly complex because they apparently can be enclosed by multiple lipid bilayers.^{33,172} The first recognizable structure is a crescent-shaped membrane that appears to be comprised of a single lipid bilayer with an external protein lattice constituted of trimers of the D13 protein.^{76,209} Initial electron microscopy studies suggested that the crescent membranes that wrap the immature virions (IV) are formed *de novo* within the virus factories,⁴² and additional high-resolution electron microscopy experiments have been interpreted as support for the conclusion that the crescents are formed from a single membrane.⁷⁸ Nevertheless, the origin, mode of formation, and composition of these crescent membranes remains controversial. Several investigators have provided evidence that these envelopes are composed of two closely apposed membranes, which are derived from the IC of the secretory pathway.^{168,198} Co-localization of IC resident cellular proteins with several vaccinia virus membrane proteins (A17L, A14L, and A13L) known to be critical for the formation of IV membranes have supported this model.^{99,185} However, subsequent studies have shown that transport of proteins from the ER to the IC and Golgi is not necessary for IV formation and that there is a transport pathway from the ER to the assembling IV.⁸² Moreover, epitope tagging of the L2 protein, an early poxvirus protein essential for crescent formation, showed that it was associated with the ER tubules throughout the cytoplasm and in some instances appeared to be continuous with the membrane crescents.¹¹⁶ The D13 protein, which forms a honeycomb lattice on the outer surface of the IVs, is critical for crescent formation and appears to act as a scaffold for their formation through its interaction with the N-terminus of the membrane-spanning A17 protein.¹⁴ Interestingly, Rouiller et al¹⁸⁰ have reported that the virus core of the related African swine fever virus core is also wrapped by specialized regions of the ER.

The process by which the nucleoprotein/transcription machinery is targeted into the immature envelopes is unclear; however, a multiprotein complex of seven viral proteins—A15, A30, D2, D3, F10, G7, and J1—appears to be critical. Repression of several of these viral products yields the same phenotype—the failure of viral membranes and viroplasm to associate with each other.²⁰⁸ Maturation of the IV to the infectious intracellular mature virus (IMV) involves a series of proteolytic cleavages of vaccinia structural proteins.³³ The mature virus particles are transported out of the assembly areas toward the periphery of the cell, where additional membranes that are derived from the

trans-Golgi or early endosomal compartments wrap them to form the intracellular enveloped virus (IEV).^{196,197} The membranes of these compartments contain vaccinia proteins that will be present in the external enveloped virus (EEV). Wrapping requires the participation of at least one protein present on the IMV and two EEV membrane proteins. It thus appears to be driven by interactions between vaccinia-encoded membrane proteins.^{15,174} It is likely then that the IEV contains at least three concentric membranes, one derived from the ER and two from the Golgi/endosome. These particles are then transported via a reorganized actin cytoskeleton (so-called actin-tails) to the plasma membrane,³⁸ where membrane fusion releases the infectious EEV form of the virus.

Modification of the Secretory Pathway Transcription and Assembly of Poliovirus on a Disassembled Secretory Pathway

Poliovirus is a nonenveloped positive sense RNA virus that modifies the host cell extensively during its replication. Once introduced into a target cell, the genomic RNA is translated into a long polyprotein precursor that contains both structural and replicative proteins of the virus (Fig. 6.11). Early in the replication of the virus, there is a massive rearrangement of the intracellular membranes into clusters of vesicles that are 200 to 400 nm in diameter.¹⁸⁶ The altered membranes appear to have characteristics of autophagosomal vesicles; they have two membranes and contain, in addition to the viral RNA replication machinery, several autophagosomal proteins, including LAMP1 and LC3. Moreover, stimulation of autophagy has been shown to increase poliovirus yield, and inhibition of the autophagosomal pathway decreased virus yield, suggesting subversion of this pathway by poliovirus.^{85,213} Electron microscopy and inhibitor studies have suggested that the induced vesicles are derived from the host cell secretory pathway, as they appear to be connected to ER membranes and both their formation and poliovirus replication are blocked by Brefeldin A.⁸³ Viral RNA transcription occurs in close association with these vesicles, and both viral RNA and viral proteins known to be required for RNA replication have been shown by electron microscopy to be associated with their cytoplasmic surface.^{12,217} Similarly, priming of RNA synthesis by the protein primer VPg appears to require membranes.²¹¹ For poliovirus, the viral precursor protein 2BC, when expressed alone, was shown to cause both membrane vesiculation and the formation of multilamellar structures²⁷; however, it is in combination with poliovirus protein 3A, which causes the inhibition of ER-to-Golgi protein traffic,⁵⁰ that membrane alterations most consistent with the pattern in poliovirus-infected cells are observed.²⁰⁶

The formation of vesicular platforms for transcription may also be necessary for efficient capsid assembly. The poliovirus capsid appears to be assembled in a sequential process in which the 5S protomers containing VP1, VP3, and VP0 assemble to form 14S pentamers, which in turn are assembled into virus capsids (see Fig. 6.11). Pentamers may associate with newly synthesized genomic RNA on intracytoplasmic vesicles and then assemble to form RNA-containing capsids on completion of the RNA. This assembly pathway is supported by immunoelectron microscopy studies showing that pentamers associated with the replication complex can, if released by detergent, rapidly assemble into empty capsids—arguing that the vesicle

FIGURE 6.11. Poliovirus assembly. The P1 precursor protein is cleaved via an autocatalytic event from the nascent polyprotein and is then cleaved twice by the 3CD-protease to yield VP1, VP2, and VP0. This cleavage is essential for assembly of the 5S monomers into 14S pentamers. It is likely that 12 of these pentamers associate directly with nascent genomic RNA that is being transcribed from membrane-bound transcriptional complexes to assemble an immature 150S provirion. Maturation cleavage of VP0 to yield VP2 and VP4 results in conversion of these immature provirions into the 160S mature virion.

prevents assembly of the capsid and keeps the pentamer in an appropriate configuration for association with the RNA.¹⁶² In this instance, poliovirus appears to have circumvented the problems of intracytoplasmic localization of replicative and structural components by utilizing a membranous organizing center.

Modification of Post-Golgi Vesicle pH by the Influenza Virus M2 Protein

The influenza HA is synthesized as a precursor protein (HA0) that in the case of the avian influenza viruses is cleaved in the trans-Golgi by furin-like proteinases to the biologically functional HA1-HA2 heterodimer, three of which in turn form the trimeric HA complex (Chapters 3, 40 and 41). The influenza virus HA present on an infecting virion is activated to its fusogenic state by the low pH of the endosome. Thus, the similarly low pH of the trans-Golgi network and post-Golgi vesicles poses a problem for the virus during the assembly phase of its life cycle, if it is to maintain HA in a functional prefusogenic form. This is apparently solved by the action of the M2 protein, a small tetrameric protein that forms cation-selective ion channels that can reduce the pH of the trans-Golgi network by pumping out hydrogen ions.^{164,205}

INCORPORATION OF THE NUCLEIC ACID GENOME DURING THE ASSEMBLY PROCESS

The processes involved in the assembly of structural components of a virus are complex and interplay intimately with those of the host cell; thus, they merely provide a mechanism by which the genomic information of the virus can be packaged into a protective environment for transfer to additional host cells. As such, the assembling virus must have evolved to efficiently select its genomic nucleic acid out of the pools of RNA and/or DNA that are present at the assembly site. Packaging of viral genomes generally involves a cis-acting sequence in the nucleic acid—the so-called packaging sequence—and a structural component(s) of the virus that can recognize and bind this element.

DNA Viruses

As described previously, for adenovirus, an empty procapsid is first formed around scaffolding proteins in a manner similar to that observed with DNA phages. Following procapsid assembly, DNA and associated core proteins are then subsequently

packaged into these empty shells to yield “immature virions” that then undergo proteolytic maturation.

Early studies indicated that *light* virus particles contain subgenomic-length viral DNA with an overrepresentation of left-end sequences. Subsequent studies showed that a cis-acting packaging sequence that is absolutely required for encapsidation of viral DNA is located within the left 390 bp of the genome. This region is highly conserved between different adenovirus subtypes and, in Ad 5, overlaps with two distinct enhancer elements for E1A transcription. Deletion of the packaging domain abrogates viability; however, infectivity can be restored by substitution of the left-end sequences at the right end of the genome.^{73,74} The packaging sequence only functions if it is within 600 bp of the inverted terminal repeat (ITS) but does not depend on the ITS itself.¹⁵² Mutational analyses showed that this packaging region contains at least seven functional AT-rich units called *A-repeats*. These repeats are functionally redundant but not functionally equivalent. Moreover, a sequence homology shared by the most important A-repeats, 5′-TTTG-N₈-CG-3′, is essential for packaging domain function. Overexpression of an A-repeat multimer competes *in trans* resulting in a dramatic decrease in viral yield without affecting DNA replication or late transcription, suggesting the involvement of limiting viral protein components in packaging.^{69,191} It seems likely from a variety of genetic analyses, *in vitro* DNA-binding studies, and chromatin immunoprecipitation approaches that the viral IVa2 protein together with the L4-22K protein bind directly to the A-repeat sequences to initiate packaging.^{54,151,153} The L1 52/55K protein, which is also critical for DNA packaging, is a part of this complex perhaps through interactions with IVa2 or L4-22K.^{153,161}

Packaging of the herpesvirus genome is equally complex. As with the large DNA phages, herpesvirus DNA replicates to yield concatemers of genomes in a head-to-tail arrangement, thus packaging must be linked to the generation of genomic-length units of DNA. In this virus, two packaging sequences—*pac1* and *pac2*—located within the terminally repeated *a* sequences appear to be important for both recognition and cleavage of the DNA (Chapters 59 and 60). As with the DNA phages, a combination of cleavage recognition sequences and *head-full* packaging appears to ensure the incorporation of unit-length genomes into the procapsid. Studies utilizing a temperature-sensitive protease mutant of HSV-1, which accumulates procapsids (containing an uncleaved scaffolding protein) at the nonpermissive temperature, although can remove the scaffold and package DNA on temperature shift to the permissive temperature, have shown that ATP is necessary for DNA packaging to occur but DNA synthesis is not.^{30,44} At least seven viral proteins—products of the genes UL6, UL15, UL17, UL25, UL28, UL32, and UL33—are required for cleavage and packaging of HSV-1 DNA. When cells are infected with HSV-1, mutants lacking the function of any of the seven genes, capsid formation, and DNA replication occur normally; however, no packaging takes place. By analogy with the DNA bacteriophages such as P22, the portal vertex, which is assembled from 12 copies of the *UL6* gene product, likely forms the docking site for these packaging proteins. Sequence analysis reveals that another critical component, encoded by the *UL15* gene, shares homology with gp17, the large catalytic subunit of the bacteriophage T4 terminase. Thus, the product of this gene, together with that of UL28, which can specifically recognize

the *pac* site, may play a direct role in the cleavage of viral DNA replication intermediates into monomers.^{1,234}

RNA Viruses

For retroviruses, genomic packaging represents a particularly difficult problem because the assembling capsid must select genomic RNAs from a large pool of viral and cellular mRNAs that are also present in the cytoplasm. Viral RNAs to be specifically packaged are identified by the presence of an RNA sequence named the packaging signal or *psi* (ψ) and are selected from the cytoplasmic pool by a specific interaction with the zinc knuckle motif(s) of the NC domain of the Gag precursor.^{41,108} The cis-acting RNA element is located at the 5′ end of the viral genome, has the capacity to mediate the packaging of heterologous RNAs, and appears to be comprised of a series of stem-loop structures that each contribute to the strength and specificity of the signal. One of the best characterized, although perhaps most complex, ψ -sequence is that of HIV-1, which is now known to span the 5′ untranslated region of the genome, as well as downstream nucleotides in the Gag region for optimal packaging efficiency. This 5′ untranslated region, which can confer packaging specificity on foreign RNAs, includes the TAR sequence that is important in Tat-mediated transcriptional control, the adjacent poly-A loop, and four stem loops that incorporate the primer binding site (PBS), the dimerization sequence (DIS), the 5′-splice donor (SD) and the packaging signal (ψ), respectively. Gag has been shown to bind specifically to this region, with PBS, DIS, and ψ stem loops each providing independent high-affinity binding sites. Disruptive and compensatory mutations within the TAR, Poly(A), PBS, DIS, and ψ elements indicate that the structure of the stem loops is important for packaging.^{31,117} NMR analyses of SL3 in the presence and absence of the NC protein have shown that tight binding is mediated by specific interactions between the amino- and carboxyl-terminal CCHC-type zinc knuckles of the NC protein and nucleotide bases of the RNA loop.^{45,108,237}

Regions of retroviral genomes that promote genome packaging often overlap with segments that promote the RNA dimerization, which is necessary for packaging of the diploid genome. Moreover, there is mounting evidence that dimerization and packaging events are intimately coupled. An elegant structural analysis by D’Souza and Summers⁴⁰ showed that dimerization of the MuLV genome results in an altered secondary structure in the *psi* region of the RNA, which exposes conserved UCUG elements that bind NC with high affinity. These elements are base paired and do not bind NC in the monomeric structure. Thus, for MuLV, the problem of ensuring the encapsidation of two genomic RNAs has been solved by linking exposure of the packaging recognition sequence to dimer formation itself. It seems likely that HIV and other retroviruses will utilize similar switches for this purpose.¹⁴⁸

Given its role in specifying genomic RNA packaging, one might expect the ψ -sequence to be located downstream of the SD site for subgenomic mRNAs. This is the case for the MuLV and reticuloendotheliosis virus ψ -sequences but not the case for HIV-1, as described earlier, or for Rous sarcoma virus (RSV). The major RNA packaging signal for HIV-2 is present on all RNA species, although this virus appears to overcome the lack of packaging signal location specificity by two novel

mechanisms—co-translational packaging and competition for limiting Gag polyprotein.⁷⁰

The cellular location in which Gag:RNA recognition occurs remains an unanswered question. Parent et al¹⁵⁶ have provided strong evidence that for RSV, genome packaging depends on Gag trafficking through the nucleus, a process that is mediated by NLS and NES signals in the MA domain of Gag.^{60,72} However, the role of nuclear trafficking of HIV-1 Gag in RNA packaging remains unresolved and controversial.^{108,156} Recent experiments by Moore et al suggest that HIV-1 RNAs form dimers preferentially in the cytoplasm and that dimerization, mediated by the DIS sequence in the genome, is critical to efficient packaging into virions.^{126,127} The incorporation of genomic RNA into assembling virions was recently imaged in live cells and showed that in the absence of Gag, genomic RNA molecules were highly dynamic and did not localize at specific sites at or near the plasma membrane. In contrast, in the presence of Gag, genomes were targeted to specific sites on the plasma membrane, where after initially exhibiting slow lateral movement they became fixed and were the site for accumulation of additional Gag molecules.^{90,92}

Genomic RNA packaging signals in other RNA viruses are less well defined. In the alphaviruses, this appears to involve direct binding of genomic RNA by the capsid protein. A short (132-nt) segment of RNA in the region of the genome encoding the nonstructural protein NS1 is critical for this interaction and for packaging of genomic RNA. As with the retroviral psi-sequence, it has also been predicted to form a series of stem-loop structures. The N-terminal third of the capsid protein is basic and unstructured in the current crystal structure. Nevertheless, a 32 amino acid region (residues 76 to 107) has been shown to be essential for RNA binding in a gel shift assay.¹⁹⁰

For segmented viruses, such as the orthomyxoviruses or the reoviruses, genomic packaging requires that a complete set of segments be packaged together in a single virus particle. For influenza virus, reverse genetic approaches have shown that the signals for transcription and replication of an RNA segment are located in the 22 5′ terminal and the 26 3′ terminal nucleotides of the RNA.¹⁰⁹ These studies do not, however, address how a full complement of RNAs is selected during assembly. Two models have been proposed to accomplish this. The random incorporation model assumes a common structural feature in all vRNPs, which enables them to be incorporated randomly into virions. Support for this model comes from the observation that an influenza A virion can possess more than eight vRNPs.^{7,52} The selective-incorporation model predicts the presence of specific structures in each vRNA segment, leading to their individual incorporation into virions. Two lines of evidence support this hypothesis: the first was data showing that defective RNA segments could inhibit the packaging of the parental segment into virions,⁵¹ and the second was the finding that viruses grown in the presence of bacterial NA and antibody to NA retained an extensively deleted NA vRNA, suggesting that the altered NA segment participates in viral replication and carries structural features required for its incorporation into virions.^{80,232} Experiments utilizing reverse genetics approaches have further supported the selective-incorporation model by demonstrating that all eight vRNA segments must be present for efficient virion formation and that sequences within the coding region of the NA vRNA encode a signal that drives incorporation of this

segment into virions.^{59,101,132} Electron microscopic studies of serially sectioned influenza virus A particles, which showed the RNPs organized in a distinct pattern (seven segments of different lengths surrounding a central segment), also support a model where the eight segments are specifically packaged.¹⁴⁵

POSTASSEMBLY MODIFICATIONS AND VIRUS RELEASE

Proteolytic Cleavage and Virus Maturation

Virus-encoded proteolytic enzymes play important roles in the process of assembly for many viruses and in a postassembly maturation step that is required for the development of an infectious particle for others. These cleavage events can act as molecular switches that introduce flexibility, as well as irreversibility, into the assembly process.

Proteolytic cleavage in the case of the alphaviruses, for example, is used to allow protein domains, translated from a single mRNA, to enter different transport pathways in the cell. The C protein, which is encoded at the 5′ end of the subgenomic 26S mRNA, folds co-translationally into an active serine proteinase that cleaves itself from the growing polypeptide chain. This releases the C protein into the cytoplasm for capsid assembly while freeing up the N-terminus of the signal peptide for the p62 glycoprotein precursor, which can then bind SRP and direct the ribosome to the ER.⁶²

In the herpesviruses, proteolytic cleavage of the scaffolding protein occurs after assembly of the procapsid is complete and is a prerequisite for DNA packaging. The scaffolding proteins of HSV-1 are encoded by a pair of overlapping genes—UL26 and UL26.5—in which the open reading frame of UL26 is an in-frame N-terminal extension of that of UL26.5. The product of the smaller gene is the abundant scaffolding protein pre-VP22a, whereas the larger gene encodes a protease precursor, which cleaves itself internally to give the proteins VP24 (protease) and VP21. Temperature-sensitive mutants in UL26 that have an inactive proteinase at the nonpermissive temperature are blocked at the procapsid stage of assembly.¹⁶⁹

A somewhat more complex proteolytic pathway is utilized by the picornaviruses to regulate the release of both structural and replicative protein components from the single polyprotein precursor that is translated from its positive-stranded RNA genome (see Fig. 6.11). The initial event in this proteolytic cascade is the primary cleavage in which the P1 structural protein precursor is separated from the P2-P3 precursor. This reaction is catalyzed by the 2A proteinase, which hydrolyzes a Tyr-Gly bond at its own amino-terminus. Whereas cleavage of the P2-P3 region is carried out by the 3C proteinase at Gln-Gly bonds, the efficient cleavage of the structural protein precursor at the VP0-VP3 and VP3-VP1 boundaries is catalyzed specifically by the 3CD precursor that includes the viral polymerase. Cleavage of the P1 precursor appears to be a prerequisite for entry of the capsid proteins into the assembly pathway. The final processing step is cleavage of VP0 to VP4 and VP2. This autocatalytic, maturational cleavage occurs late in the assembly pathway and appears to be linked to encapsidation of the viral RNA genome. It is likely that the structural alterations that accompany the cleavage event both stabilize the capsid and irreversibly commit the virus to the conformational changes

induced on receptor binding that are necessary for productive infection of cells.⁷⁵

A similar maturational cleavage is required following assembly and envelopment of retroviral capsids. As we described earlier, the retroviral capsid is assembled from polyprotein precursors that are encoded by the *gag* gene. The viral aspartyl proteinase is encoded by the *pro* region of the genome and is translated from unspliced, genome-length RNA by a ribosomal frameshift mechanism as a Gag-Pro or Gag-Pro-Pol precursor protein (Chapters 47 and 49). The presence of the Gag sequences ensures that this key enzyme is targeted to and incorporated into the assembling capsid. The mechanism by which the protease is activated late in the assembly process (most probably after envelopment is complete) is not known. Because the active enzyme is a homodimer of two protease subunits, it has been postulated that dimerization of proteinase precursors in the nascent capsid might allow a functional enzyme to form. However, in the betaretroviruses, the immature capsid contains a full complement of proteinase precursors, which are not activated until late in envelopment at the plasma membrane. Immature capsids of the betaretrovirus M-PMV are stable when isolated from infected cells; however, the protease can be activated to cleave the assembled precursors to their mature products by treatment with the reducing agent dithiothreitol, suggesting that modification of cysteine residues might act to regulate the initiation of proteolysis.¹⁵⁷

Cleavage of the Gag precursors in the immature capsid is accompanied by a major morphological rearrangement in which the mature NC protein condenses the genomic RNA inside a CA shell (see Fig. 6.7)—the electron dense core structure of the virus seen in electron micrographs.⁶⁵ Cleavage at the N-terminus of CA induces a conformational change in the protein that allows the newly freed N-terminal proline to form a charge pair with a nearby aspartic acid, redirecting assembly from a *spherical* immature capsid to assembly of the cylindrical or cone-like core shell structure.^{139,223} Maturational cleavage, as in the case of poliovirus, results in an irreversible commitment to the entry pathway. It prevents a simple reversal of the assembly process and presumably, through the formation of the core, allows the rearrangement of RNA and the reverse transcriptase into a conformation that is optimal for reverse transcription of the genome. In the absence of cleavage, reverse transcription cannot occur and the virions are noninfectious.²⁰⁷

Adenoviruses, like retroviruses, undergo a maturational cleavage after assembly that is essential for infectivity. The immature virions formed after DNA packaging contain five precursor proteins that must be processed before the mature infectious virion is produced. These include components of the core and the preterminal protein (pTP) used to initiate DNA synthesis. The 23kD adenovirus proteinase, which is encoded by the L3 region of the genome, is inactive in its purified form. It requires an 11 amino acid peptide present at the carboxy-terminus of pVI and viral DNA as co-factors for its activity. This unique use of DNA as a co-factor ensures that proteolytic maturation of the virus cannot take place until packaging of DNA is complete.^{39,112}

Budding: Role of Viral and Cellular Proteins in Membrane Extrusion

It is clear from the discussions in previous sections that various strategies are utilized by different enveloped viruses to mediate

the process of membrane extrusion that we have termed *budding*. Envelopment by a lipid bilayer fulfills two functions for a virus: it provides a protective outer layer into which can be embedded the necessary machinery for target cell attachment and entry, and, in most cases, it releases the virus into an environment that is topologically equivalent to the exterior of the cell. The strategies used to drive the budding process can be classified into three general mechanisms.⁶¹ In the first, membrane extrusion is driven by envelope glycoproteins alone. This is exemplified by the E protein of the coronaviruses that is capable of inducing the release of VLPs in the absence of an RNP. The second strategy is that used by the retroviruses where the capsid precursors, in the absence of the viral glycoproteins, are able to efficiently induce membrane extrusion and particle release. In this instance, it is hypothesized that the tight interaction between the MA domain of Gag and the lipid bilayer, coupled with the force of Gag-Gag interactions in assembly, drives the budding process. The third mechanism is that of the alphaviruses, which involves interactions between the viral glycoprotein spikes and the assembled capsid. In this case, neither the glycoproteins nor the capsid alone can mediate budding. It appears that lateral interactions between the glycoproteins, coupled with cytoplasmic domain-capsid connections, progressively bend the membrane to form the spherical particle.⁶²

For all of these mechanisms, the final step of budding—the process of pinching off—requires a membrane fusion event. For several viruses, it is now clear that this is a separable event that requires the involvement of both viral and host components. Experiments in HIV have shown that deletion of the p6 domain at the C-terminus of Gag results in a block to virus release at the pinching off stage,⁶⁸ and it is now understood that diverse retroviruses encode functionally equivalent Gag *late function* or L domains that are required for efficient release of virions.^{48,130} Viral L domains fall into three classes based on their characteristic tetrapeptide sequence motifs—Pro-Thr/Ser-Ala-Pro (PTAP or PSAP), Pro-Pro-X-Tyr (PPXY), and Tyr-Pro-(X)_n-Leu [YP(X)_nL]. In many instances, these viral L domains are functionally interchangeable and can mediate pinching off of the virion even when positioned at different locations in Gag.^{155,236} Evidence has accumulated over the past several years that these motifs interact with components of a complex cellular machinery that is used in the biogenesis of an endosomal compartment known as the multivesicular body (MVB). Unlike other mechanisms used by the cell to form and pinch off vesicles into the cytoplasm, this machinery facilitates the pinching off into the MVB of exosomes that have the same topology as virus. This process is mediated by a complex and highly conserved protein network—the endosomal sorting complex required for transport (ESCRT) machinery—which exists in all eukaryotes and consists of five hetero-oligomeric complexes (ESCRT-0, ESCRT-1, ESCRT-II, ESCRT-III, and VPS-4).^{11,114,227} Components of this complex also appear to be involved in the last stage of cytokinesis, termed *abscission*, where, as with virus release, a membranous stalk must undergo membrane fission to release the two daughter cells.^{23,128} Recent studies have shown that the ESCRT-0 complex functions to concentrate ubiquitinated cargo on endosomal membranes; the ESCRT-I and -II complexes together induce bud formation while remaining outside the vesicle; and the ESCRT-III complex

mediates membrane scission from the cytosolic side of the bud.²³⁰ Mammalian ESCRT-III is formed by charged multivesicular body proteins (CHMPs), a family of structurally related but highly divergent α -helical proteins that has 12 known members in humans.^{114,227}

The initial indication that retroviral budding and this machinery were linked came from the observation that the ESCRT-I component Tsg101 interacted with p6 and that this interaction depended on the PTAP motif.⁶³ A Tsg101 interacting protein, AIP1, which can also interact directly with ESCRT-III, has been shown to interact with the YP(X)_nL motif in both equine infectious anemia virus and HIV.^{115,201} It is less clear how Gag proteins, which contain the PPXY motif, enter the pathway. These proteins interact with Nedd4 family members that are ubiquitin E3 ligases involved in the covalent attachment of ubiquitin to membrane-associated proteins.^{184,233} Monoubiquitination has been shown to direct the modified protein to the MVB and likely functions to link PPXY L-domain proteins to the ESCRT machinery.¹³⁰

In addition to those L-domains that play a major role in virus release, it is becoming clear that in several viruses, multiple auxiliary L-domains are present that can augment the process. In HIV-1, for example, there is evidence that the PTAP motif acts synergistically with ALIX-binding sequences at the C-terminus of p6 to optimize release.¹¹⁴ Through these disparate and still incompletely understood mechanisms^{114,227} viruses recruit components of ESCRT-III to the site of budding to mediate the process of membrane scission. Only a subset of the 12 proteins known to make up the ESCRT-III complex may be involved, as a recent study demonstrated that the co-depletion of CHMP2 or CHMP4 family members profoundly impairs HIV-1 release, whereas other CHMPs are not required.¹²⁹

The ATPase vacuolar protein sorting 4 (VPS4) acts at a late stage of ESCRT function, providing energy for ESCRT disassembly. Recent live cell imaging studies reveal that ESCRT-III and VPS4 are rapidly and transiently recruited before HIV-1 particle release, supporting the notion that VPS4 has a direct role in HIV-1 budding.^{9,93} Overexpression of a dominant negative mutant of this protein inhibits the budding of several retroviruses that encode each of the tetrapeptide motifs, arguing that divergent retroviruses all depend on the ESCRT sorting complex.^{115,224}

What is now clear is that retroviruses are not the only virus family that interact with this cellular pathway. Late domain motifs that facilitate release of virions have been identified in the structural proteins of the filoviruses,⁸⁷ rhabdoviruses,³⁵ arenaviruses,^{160,203} and paramyxoviruses,¹⁹² suggesting that divergent virus families have adopted a common mechanism for this late stage in enveloped virus budding.

Influenza virus is an exception to this widespread dependence on the ESCRT machinery.²¹ Rossman et al¹⁷⁷ showed that for this virus, it is the viral M2 protein, rather than a host component, that mediates virus membrane scission. During morphogenesis, the M2 protein localizes to the neck of budding virions, and a highly conserved amphipathic helix in the cytoplasmic tail appears to mediate a cholesterol-dependent alteration in membrane curvature. Mutation of the amphipathic helix results in failure of the virus to undergo membrane scission and virion release.^{177,178} Thus, it is possible that viral proteins such as M2 are able to mimic the functions of the

ESCRT III machinery by constricting the viral membrane and inducing the scission events required for virus release.

Mechanisms to Facilitate the Release of Nascent Particles

If viruses are to efficiently travel to an uninfected target cell, they face one last hurdle following envelopment and release. This is the need to avoid rebinding to receptors on the producing cell. For viruses such as the ortho- and paramyxoviruses, which utilize sialic acid as a receptor on the cell surface, this problem is circumvented by the incorporation of a receptor-destroying enzyme, a sialidase, which can remove these residues during transit through the secretory pathway. For influenza virus, the NA is critical for virus release because, in its absence, nascent virus binds to both the cell surface and other virions in large aggregates.¹⁰⁴

Retroviruses have similarly evolved mechanisms to facilitate release and thereby reduce superinfection of a cell. Cells infected with one retrovirus are generally resistant to subsequent infection by a second virus of the same receptor class. The presumed mechanism for this viral interference is the synthesis of viral glycoproteins in large excess over the levels that are incorporated into virions with the effect that cellular receptors that are transported to the cell surface are already occupied by their ligand. This results in removal or down-regulation of the receptor from the cell surface. For HIV-1, down-regulation of the primary receptor CD4 seems to be crucial, because the virus has evolved two additional mechanisms to ensure this. Two of the accessory proteins encoded by HIV—Vpu and Nef—act by binding CD4 in the ER and at the cell surface, respectively, and targeting the receptor for degradation (Chapter 49).

Independent of this need to down-regulate viral receptors, recent work has demonstrated that virus escape from the cell surface, the last step of the replication cycle, is effectively targeted by a host cell restriction factor, tetherin (also known as BST2 or CD317). This protein was initially identified as the factor responsible for the block to virion release from certain cell types infected by HIV-1 mutants lacking the accessory gene *vpu*.^{11,114,138,218} Tetherin can be induced by type I interferon and other proinflammatory stimuli and has an unusual topology in which the extracellular domain forms an extended parallel coiled-coil that is anchored at the N-terminus by a protein transmembrane domain and at the C-terminus by a glycosyl phosphatidylinositol GPI anchor. Biochemical and structural data favor a model where parallel tetherin dimers crosslink virions to the plasma membrane or the membrane of other virions.^{11,114} Tetherin can restrict the release of all retroviral particles tested to date, including those of the spumavirus and betaretrovirus families, which preassemble capsids in the cytoplasm. In addition, mammalian tetherins block release of a variety of membrane viruses, including filoviruses, arenaviruses, rhabdoviruses, and at least one herpesvirus.^{53,91} In turn, viruses have evolved countermeasures that have allowed them to overcome this inhibition of release. The Vpu protein of HIV-1 is the prototypical antagonist to tetherin and interacts through the transmembrane region to mediate down-regulation and lysosomal degradation of the host restriction factor. In the case of SIVs, this function is primarily carried out by the Nef protein, although in some instances, as in HIV-2 or Ebola virus, it can be mediated by the viral glycoprotein.⁵³ Given the

diversity of mechanisms utilized to counteract tetherin, it is clear that this last step of the life cycle is critical to the virus. Indeed, the evolution of primate lentiviruses, particularly pandemic HIV-1, has been shaped by species-specific differences in this host cell restriction factor.¹⁸⁸

Why Do Viruses Transform Cells?

GENERAL PRINCIPLES OF VIRAL TRANSFORMATION

In 1908, Ellerman and Bang¹⁴³ reported that cell-free filtrates from chickens with leukemia could transmit the disease to healthy birds. The ability of the causative agent to pass through a fine filter identified it as a virus, providing the first evidence that viruses could cause cancer as well as acute contagious diseases. Three years later, Peyton Rous³⁸² showed that a solid tumor in chickens, sarcoma, could also be transmitted by cell-free filtrates. In the 100 years since these discoveries, tumor viruses have been studied intensely in the belief that thorough understanding of these relatively simple agents

would provide mechanistic insight into carcinogenesis, identify the causes of some human malignancies, and suggest novel strategies to prevent and treat cancer. All of these expectations have been met. Tumor viruses dysregulate or exploit crucial regulatory nodes in cells in order to replicate and persist in their host. Because these nodes regulate cell proliferation and survival, these viruses can cause cancer. Furthermore, because of their intimate association with this central cellular machinery, tumor viruses have proven to be prime tools for unraveling the complexities of all human cancers, not just those induced by viruses themselves. For example, studies of tumor viruses led to the discovery of cellular oncogenes and tumor suppressor proteins and to the elucidation of many important aspects of signal transduction, cell cycle control, cellular biochemistry, and carcinogenesis. Indeed, the concept that cancer is a genetic disease emerged largely from studies of tumor viruses. We have also learned that tumor viruses are associated with specific types of human cancer and that tumor virus infection is responsible for approximately 15% of human cancer deaths.³¹⁰ Vaccines have been developed and deployed that prevent infection by certain tumor viruses and inhibit the formation of precancerous lesions or cancers.⁴⁰³ The remarkable success of these endeavors is due to the efforts of generations of virologists, biochemists, molecular biologists, epidemiologists, and clinicians, and to the favorable properties of the viruses themselves.

Cell Transformation

Early studies of tumor viruses focused on isolation of viruses from naturally occurring tumors in animals and description of the effects of these viruses in experimental animals. These studies revealed that a wide variety of viruses can induce tumors (Table 7.1). Diverse taxonomic groups of viruses with DNA genomes can cause tumors: polyomaviruses, papillomaviruses, adenoviruses, herpesviruses, hepadnaviruses, and poxviruses. Among the RNA viruses, a subset of retroviruses cause tumors in animals, and Hepatitis C virus has been implicated in human cancer. Thus, the ability to induce tumor formation is not associated with a particular class of virus or mode of virus replication. The types of tumors induced by viruses are also diverse and include sarcomas (tumors of mesenchymal cells), leukemias and lymphomas (tumors of hematopoietic cells), and carcinomas (tumors of epithelial cells).

Although such experimental pathogenesis studies revealed many fascinating and complex features of viral tumorigenesis, experiments in animals are cumbersome, slow, expensive, and often poorly suited for biochemical and mechanistic analysis. Therefore, cultured cell models of tumorigenesis are widely used. Cells explanted from tumors display many properties that

TABLE 7.1 **Oncogenic Viruses**

Taxonomic grouping	Examples	Primary tumor types
RNA viruses		
<i>Flaviviridae</i>	Hepatitis C virus (HCV)	Hepatocellular carcinoma
<i>Retroviridae</i>		
Alpharetroviruses	Avian leukosis and sarcoma viruses Rous sarcoma virus (RSV) Rous-associated viruses (RAV) Avian acute leukemia viruses Avian myeloblastosis virus (AMV) Avian erythroblastosis virus (AEV) Myelocytoma virus MC29	Sarcoma B-cell lymphoma, erythroleukemia Myeloid and/or erythroid leukemia Erythroid leukemia Myeloid leukemia
Betaretroviruses	Mouse mammary tumor virus (MMTV) Jaagsiekte sheep retrovirus	Mammary carcinoma Lung carcinoma

Deltaretroviruses	Human T-lymphotropic virus (HTLV) Bovine leukemia virus	Adult T-cell leukemia B-cell leukemia
Epsilonretroviruses	Walleye dermal sarcoma virus	Sarcoma
DNA viruses		
<i>Adenoviridae</i>	All types	Various solid tumors
<i>Hepadnaviridae</i>	Hepatitis B virus (HBV)	Hepatocellular carcinoma
<i>Herpesviridae</i>	Epstein-Barr virus (EBV)	Burkitt lymphoma (African) Nasopharyngeal carcinoma
	Kaposi sarcoma herpesvirus (KSHV)	Kaposi sarcoma
<i>Polyomaviridae</i>	SV40, polyomavirus	Various solid tumors (parotid gland tumors, mammary carcinoma)
<i>Papillomaviridae</i>	Human papillomavirus (HPV), bovine papillomavirus	Papillomas, carcinomas
<i>Poxviridae</i>	Shope fibromavirus	Myxomas, fibromas

distinguish them from normal cells. Collectively, these properties are referred to as the transformed phenotype (Table 7.2), and cells displaying these properties are called transformed cells. Infection of normal cells in culture with many (but not all) tumor viruses can cause the rapid acquisition of the transformed phenotype, a process called transformation. The most commonly used cell types for transformation studies are rodent fibroblasts, which in general are easier to transform *in vitro* than human cells.

The most striking property of transformed cells is their ability to form tumors when inoculated into animals. Experiments in animals have classically been used to determine whether a virus can cause a tumor in a living organism and to identify the viral gene(s) responsible for this activity. Although mice are used for the vast majority of such experiments, other commonly used hosts are rats, hamsters, rabbits, and monkeys. Immunodeficient animals (e.g., athymic nude mice) are frequently used in order to avoid immune rejection of the inoculated cells.

In addition to tumorigenicity, transformed cells display a variety of features in culture that distinguish them from normal cells. These include changes in growth, morphology, metabolism, and intracellular and cell surface biochemistry. Normal cells have very stringent requirements for growth. To proliferate in culture, normal cells require peptide growth factors, commonly supplied as fetal bovine serum. When plated on plastic, normal adherent cells typically divide to fill the available space on the surface of the culture vessel until they become a confluent monolayer of cells and then cease proliferation, even if supplied with adequate amounts of nutrients and growth factors. The cessation of growth at confluence is known as density-dependent growth inhibition or contact inhibition. Most normal cells also require attachment to a solid substrate and are unable to grow when suspended in semisolid medium such as agarose or methylcellulose, a property known as anchorage dependence. Finally, normal cells usually display a limited life span in culture after isolation from an animal and can be serially passaged for no more than a few months before they

TABLE 7.2 Properties of Transformed Cells

	Normal cells	Transformed cells	Behavior of transformed cells in the laboratory
Growth	Nontumorigenic	Tumorigenic	Form tumors upon inoculation into susceptible animal hosts
	Finite life span	Immortal	Indefinite life span in culture
	Contact inhibition	Loss of contact inhibition	Increased saturation density
	Anchorage dependent	Anchorage independent	Focus formation
	Growth factor dependent	Growth factor independent	Colony formation in semisolid medium
Biochemical	Normal nutrient transport	Increased nutrient transport	Growth in reduced concentration of growth factors or serum
	Oxidative respiration	Aerobic glycolysis (Warburg effect)	DNA synthesis despite nutrient deprivation
Acidification of culture medium			
Other changes in transformed cells include:			
<ul style="list-style-type: none"> • Decreased levels of fibronectins, decreased adhesion to solid substrates, and loss of stress fibers • Increased agglutination by lectins and synthesis of cell surface proteases • Redistribution of microfilaments and altered morphology 			

cease proliferation and adopt a permanently growth-arrested state called senescence.

Transformed cells display strikingly different growth properties than normal cells (Table 7.2). Transformed cells have minimal requirements for growth factors and can proliferate in low concentrations of serum (or even in its absence). Transformed cells continue to proliferate after reaching confluence and display a multilayered, piled-up appearance and higher saturation densities than normal cells (Fig. 7.1). If a transformed cell is present in an excess of normal cells in a culture, it will override contact inhibition at confluence and continue to proliferate locally, forming a discrete, clonal group of transformed cells known as a focus (Fig. 7.1).¹⁹⁸ Because each focus originates from a single transformed cell, the number of foci formed provides a convenient measure of the number of transforming viruses in an inoculum. In addition, because foci are readily apparent on a background monolayer of cells, focus formation provides a simple means of identifying and isolating transformants. Transformed cells also display anchorage independence and can form colonies in semisolid medium without adhering to a solid surface.²⁹⁴ Anchorage independence is the property of transformed cells that is most closely associated with the ability to form tumors in animals. Finally, in contrast to normal cultured cells, transformed cells that divide indefinitely in culture are said to be immortal.

Transformed cells can also display striking morphologic differences from normal cells due to changes in the cellular cytoskeleton, extracellular matrix, and cell surface.^{226,371} Transformed cells also switch from oxidative respiration to aerobic glycolysis, a phenomenon known as the Warburg effect. The resulting lactic acid production and acidification of the culture medium (and the tell-tale yellow of medium containing phenol red, a pH indicator) allows the rapid identification of transformed cultures.

It should be noted that transformation is not an all-or-nothing phenomenon. Some transformed cells display only a subset of these properties. For example, in some cases cells can form foci but fail to display anchorage independence or tumorigenicity, or they can display reduced serum requirements

but not form foci. It is therefore important to specify the assay used to assess transformation. “Normal” established cell lines, such as murine NIH3T3 cells, are immortal but do not display other features of transformed cells and thus can be regarded as being minimally transformed.

Identification of Viral Oncogenes

To determine whether a virus has tumorigenic or transforming activity, host animals or cells are infected and the appearance of tumors or the acquisition of a transformed phenotype in culture is measured. Acute transforming retroviruses cause the rapid formation of tumors in animals and rapidly transform cells in culture because they carry genetic information known as oncogenes. In contrast, retroviruses that lack oncogenes cause tumors in animals many months after infection and do not transform cells in culture. Most DNA tumor viruses contain oncogenes and can transform cells in culture and induce tumors in animals.

For viruses that contain oncogenes, cell transformation typically occurs within a few days or weeks of infection, although some measures of transformation, such as cell immortalization, take months to assess. When infected at high multiplicity of infection (moi), the entire culture of cells may undergo transformation, which can allow biochemical characterization of cell transformation. Infections at low moi require the use of quantal measures of transformation, such as focus formation or colony formation in agarose, to score transformation because most cells in the culture remain normal.

Although acute properties of transformation are fairly easy to elicit, for some viruses stable transformation that persists in culture is a very rare event. In addition, for lytic DNA viruses, where replication is cytocidal, transformation can only occur when the virus life cycle cannot go to completion. Transformation by these viruses is commonly studied following infection of nonpermissive cells that cannot support a full virus life cycle. In these cells, the initial steps (the early phase) of virus infection take place—virus attachment to cells, penetration into the cells, virion uncoating, and expression of the early proteins—but then

FIGURE 7.1. Appearance of transformed cells. **A:** Plate showing a monolayer of normal murine C127 fibroblasts. **B:** Plate of fibroblasts showing transformed foci induced by transfection with bovine papillomavirus DNA. **A** and **B** were stained 12 days after transfection. **C:** Micrograph of a monolayer of normal murine fibroblasts, showing flat, spread-out morphology. **D:** Culture of murine fibroblasts transformed by the bovine papillomavirus E5 protein. Note the piled-up, refractile appearance of small, transformed cells.

productive infection is aborted before the onset of vegetative viral DNA replication. For example, rat and mouse cells are nonpermissive for replication by simian virus 40 (SV40), a monkey virus, so many transformation assays are conducted in these cells. Alternatively, permissive cells, in which the wild-type virus can complete its life cycle, can be transformed if viral replication is blocked. Infection with replication-defective viral mutants or transfection with nonreplicating, subgenomic viral DNA fragments that contain viral oncogenes can transform permissive cells.²⁹⁹ In addition, some tumor viruses (such as herpesviruses) can establish latency in permissive cells, and in some cases expression of a subset of viral genes in the latently infected cells can lead to transformation. Infection by acute transforming retroviruses usually does not result in cell death, and stable transformation is very efficient, with virtually every infected cell becoming transformed.

An oncogene can display potent activity in one transformation assay but be totally devoid of activity in another assay, even in the same host cell, because it may modulate multiple independent cellular signaling pathways. Host-specific differences can also greatly influence transforming activity, so a variety of host animals or cells are commonly tested to assess transforming activity. Some oncogenes have potent transforming

activity in numerous assays but are unable to cause cell immortalization. Therefore, transformation is often studied in established cell lines that are already immortal.

Viral mutants can be used to identify specific viral genes with transforming activity. In early experiments, mutagenized viral stocks were tested for loss of transforming activity or for the acquisition of temperature-sensitive transforming activity. The generation and analysis of conditional mutants were particularly useful for identifying and studying transforming genes, especially those that are essential for virus replication.^{380,467} In these situations, the virus is first propagated under permissive conditions, and then the virus is used to infect cells under nonpermissive conditions and transformation is assessed. Genetic mapping approaches can then be used to identify the mutant viral gene responsible for the transformation defect. More recently, specific mutations were constructed in individual viral open reading frames, and the resulting virus mutants were assayed for transforming activity. Alternatively, individual viral genes or subgenomic segments can be introduced into cells or transgenic animals and assessed for transforming activity or tumorigenicity.^{192,420} This approach is complicated when more than one viral oncogene is required for transformation, because no single gene displays

activity. In these situations, combinations of viral genes can be transferred into cells, or the ability of viral genes to cooperate with cellular oncogenes can be tested.

The analysis of murine polyomavirus transforming functions illustrates some of the power and pitfalls of these approaches. Murine polyomavirus (hereafter called polyomavirus) is related to SV40. SV40 and polyomavirus express the early protein, large T antigen (LT), which is required for viral DNA replication. Certain mutations in the SV40 *LT* gene caused temperature-sensitive defects in cell transformation as well as viral DNA replication, identifying the *LT* gene as the major oncogene of SV40.² However, the equivalent polyomavirus LT mutants were temperature sensitive for virus replication but, at least under some conditions, able to transform cells at the nonpermissive temperature. In addition, the polyomavirus *LT* gene was often disrupted in transformed cells. These findings suggested that, in contrast to SV40, LT was not the major transforming protein of polyomavirus. Indeed, Benjamin²⁶ isolated transformation-defective polyomavirus mutants that could replicate in mouse cells that had been transformed by wild-type polyomavirus, but not in normal mouse cells, so-called *host-range-restricted* and *transformation-defective* (hr-T) mutants. Genetic mapping revealed that the hr-T mutant phenotype resulted not from mutations in the *LT* gene but rather from mutations in an alternative open reading frame in the early region of polyomavirus, which encoded a distinct protein, middle T antigen (mT) (e-Fig. 7.1). SV40 does not encode mT. These findings indicated that SV40 and polyomavirus, though genetically similar, used different mechanisms to transform cells.

To determine the activities of the individual early proteins of polyomavirus, a panel of complementary DNA (cDNA) clones that each expressed a single viral protein was assayed in rat1 cells, an established cell line. The clone expressing polyomavirus mT antigen alone was the only one that displayed transforming activity: cells expressing mT antigen formed foci, appeared morphologically transformed, and formed tumors in animals.⁴⁶⁸ These results implied that mT is the major transforming protein of polyomavirus. However, cells transformed by mT antigen were unable to grow in low serum and were thus only partially transformed. On the other hand, cells expressing polyomavirus LT alone were able to grow in low serum, even though they did not display other properties of transformed cells.³⁷³ By using a different assay to study polyomavirus transformation, namely, the ability of the viral genes to convert primary rat embryo fibroblasts into immortalized cells, Rassoulzadegan et al³⁷⁴ found that LT was active while mT was not. Furthermore, sequential transfer of the *LT* and *mT* genes could convert primary cells into immortal, fully transformed cells. Thus, the individual oncogenes of polyomavirus displayed different transforming activities. Together, these important experiments identified the polyomavirus oncogenes, revealed that they had different effects on cell growth, demonstrated that oncogenes can cooperate to generate fully transformed cells, and highlighted the critical importance of the particular assays used to assess transformation.

Another approach to identify viral oncogenes rests on the finding that genes responsible for transformation are frequently retained in transformed cells, whereas the other viral genes can be lost. Thus, DNA virus genes that are uniformly expressed in transformed cells are likely to be viral oncogenes.

Experiments searching for viral DNA and RNA in transformed cells led to the presumptive identification of E1A and E1B as the primary adenovirus oncogenes.^{123,167} As the roster of viral and cellular oncogenes has expanded, it is now often possible to identify viral oncogenes by comparing the sequences of viral genes to sequence databases, because novel viral oncogenes are often homologous to validated oncogenes.

The mapping experiments outlined previously demonstrated that DNA tumor viruses typically contain multiple oncogenes. In contrast, acute transforming retroviruses usually contain one oncogene, although there are examples of retroviruses with two (e.g., avian erythroblastosis virus [AEV] ES4 contains both *ErbA* and *ErbB* oncogenes). Nonacute retroviruses lack oncogenes.

Maintenance of Transformation

Is continuous expression of viral oncogenes required to maintain the transformed phenotype, or do tumor virus oncogenes only initiate cell transformation, after which they are not required (a hit-and-run-type mechanism)? If viral genes are required to maintain transformation, then they will be expressed in stably transformed cells. Biochemical and immune-based analysis can detect the presence of viral genes and proteins in cells transformed by many viruses, but often only a subset of viral genes is expressed in these cells. The production of infectious virus by transformed cells would provide definitive evidence for the presence of an intact, functional viral genome in the cells, but one of the striking properties of virally transformed cells is that they often do not produce infectious virus. This is not surprising for viruses, including many of the DNA tumor viruses, whose transforming activity is typically studied in nonpermissive cells unable to support virus replication. In contrast, cells transformed by Rous sarcoma virus or some other retroviruses produce infectious virus.

The presence of wild-type virus genomes in transformed cells was demonstrated by virus rescue experiments. In a typical experiment, SV40-transformed mouse cells (which are nonpermissive for replication of SV40) were fused to nontransformed, permissive monkey cells (e-Fig. 7.2). The fused cells produced infectious wild-type SV40, which could be detected by plaque formation assays in permissive cells.²⁶⁶ This demonstrated that transformed cells could contain full-length, infectious virus genomes in a latent state, which could be activated by replication factors present in permissive cells. We now know that the inability of mouse cells to support SV40 replication is due to the inability of murine DNA polymerase- α /primase to interact with SV40 LT.⁴⁰⁸

The study of conditional viral mutants and expression constructs proved that viral genes expressed in transformed cells are required to maintain the transformed state. In these experiments, cells transformed under the permissive condition when the viral oncoprotein was active often reverted to normal under nonpermissive conditions that inactivated the oncoprotein. This was initially shown with temperature-sensitive mutants of viral oncogenes, where transformation was extinguished at the higher, nonpermissive temperature.^{27,302,416} More recently, individual oncogenes driven by inducible/repressible promoters or maneuvers such as RNA interference were used to show that viral oncogene expression was required to maintain the transformed phenotype. Ongoing oncogene expression is not required in cells transformed by all viruses, but it is commonly

observed for cells transformed by a variety of DNA viruses and acute transforming retroviruses.

Continuous oncogene expression is also required for cells derived from some virally induced human tumors. For example, repression of human papillomavirus (HPV) oncogene expression in cervical cancer cells causes the rapid cessation of proliferation or the induction of apoptosis (e.g., reference [225]). Thus, even though mutations presumably accumulated in these cells during the extended period of human carcinogenesis, these mutations are not sufficient to maintain the transformed phenotype in the absence of viral oncogene expression. This finding raises the hope that it will be possible to treat virally induced cancers by interfering with the expression or action of viral oncogenes.

To continuously provide viral oncogene products in stably transformed cells, the viral genome must persist. Most commonly, the viral DNA is covalently integrated into the cellular DNA and replicates passively with the host genome. For retroviruses, integration of an essentially intact viral genome is an integral step in the viral life cycle, but for most DNA viruses, integration is incidental (and indeed inimical) to normal viral DNA replication. For these viruses, integration does not occur at specific sites in the cellular genome, and often only portions of the viral genome containing the viral oncogenes are present in the cell. Integration of DNA virus genomes is a rare event, which may explain at least in part why stable transformation by these viruses is so inefficient. Papillomavirus and herpesvirus genomes stably replicate as plasmids in transformed cells, but the DNA of these viruses can be integrated in cancer cells.

Origin of Viral Oncogenes

Where do viral oncogenes come from? Initial studies with retroviruses were conducted with Rous sarcoma virus (RSV). Cells transformed by infection with a mutant RSV carrying a temperature-sensitive *src* gene rapidly reverted to a nontransformed phenotype when shifted to the nonpermissive temperature, but the mutant was replication competent at both high and low temperatures.^{74,302} Similarly, transformation-defective RSV deletion mutants were isolated that retained the ability to replicate.²⁷ These important results indicated that a specific gene (*src*) was responsible for RSV transformation but not for virus replication. Stehelin, Varmus, and Bishop⁴⁴¹ later used molecular hybridization to show that *src* sequences were actually derived from chicken cell DNA. We now know that acute transforming retroviruses such as RSV incorporate altered versions of cellular genes into the viral genomes, a process known as transduction. These transduced genes typically encode constitutively active versions of cellular signal transduction components, such as growth factor receptors and other signaling proteins (see next section). The cellular versions of these genes (designated by the prefix *c*, e.g., *c-src*) are known as the proto-oncogenes, whereas the active viral versions (e.g., *v-src*) are called oncogenes.⁸⁶ In contrast, the nonacute retroviruses induce tumors by integrating near-cellular proto-oncogenes and activating their expression.

The discovery that cellular proto-oncogenes can be activated by viruses to generate cancer suggested that nonviral cancers might also arise by activation of proto-oncogenes. Indeed, spontaneously arising human tumors frequently contain altered or overexpressed versions of the proto-oncogenes targeted by oncogenic retroviruses. In several cases, drugs have been developed that specifically inhibit activated proto-oncogene products and provide substantial clinical benefit to

cancer patients (e.g., in chronic myelogenous leukemia and lung cancer). Thus, the practical legacy of tumor virology extends far beyond virally induced tumors.

In contrast to most retroviral oncogenes, the oncogenes of the small DNA tumor viruses are intrinsic viral genes required for virus replication, and mutations that interfere with transforming activity usually also inhibit viral replication. In some cases, phylogenetic analysis shows that these genes have been essential for virus replication for millions of years. DNA virus oncogenes usually encode proteins that bind and modulate cellular proteins that regulate cell growth. Most commonly, nuclear oncoproteins of a number of DNA tumor viruses bind to the p53 and retinoblastoma (Rb) tumor suppressor proteins and neutralize their growth inhibitory activity, but the oncoproteins of DNA tumor viruses can modulate other cellular targets as well. Some DNA virus oncoproteins mimic constitutively active forms of a cellular regulatory protein.

p53 and Rb are not only targets of viral tumorigenesis. Most sporadic human cancers, as well as some inherited cancers, contain inactivating mutations in the *p53* and *Rb* genes and in genes in the pathways they control.²⁸⁴ As was the case with the discovery of cellular proto-oncogenes, studies of DNA tumor viruses identified cellular proteins and pathways crucial for understanding the genetic basis of naturally occurring, nonviral tumors.

Although retroviral oncogenes usually have cellular origins and DNA tumor virus oncogenes typically have viral origins, these distinctions are not absolute. The Jaagsiekte sheep retrovirus envelope protein is required for both virus replication and cell transformation, and the gp55P oncoprotein of the Friend erythroleukemia retrovirus is a mutant retroviral envelope protein that contributes to erythroleukemia in mice.^{285,296} On the other hand, the genome of Kaposi sarcoma herpesvirus (KSHV), a large DNA-containing virus, contains a number of genes essential for viral replication and cell transformation that appear to have been acquired from the cellular genome in relatively recent evolutionary times.^{328,389}

Cellular Targets of Viral Oncogenes

The great majority of viral oncogenes stimulate cell proliferation (most of the others inhibit cell death). In untransformed cells, the cell division cycle is regulated by intrinsic oscillators, which ensure the orderly progression of the cell cycle, and by external growth factors, which indirectly affect the activity of the cell cycle machinery. Like serum growth factors, many viral oncogenes can stimulate DNA synthesis in normal cells made quiescent by serum starvation. Thus, the signal transduction pathways activated by growth factors provide a useful framework to understand the function of viral oncogenes (Fig. 7.2).

Serum contains polypeptide growth factors such as platelet-derived growth factor (PDGF) and epidermal growth factor (EGF), which bind to specific cell surface receptors to initiate mitogenic signaling. These growth factor receptors are often transmembrane proteins with an extracellular ligand binding domain, a membrane-spanning domain, and an intracellular signaling domain. Ligand binding induces dimerization and/or reorientation of the receptors, initiating intracellular signaling cascades.⁴⁰⁷ Many of these receptors are tyrosine kinases or associate with tyrosine kinases. The molecular events induced by ligand binding result in activation of the intrinsic tyrosine kinase activity of the receptors (or of the associated kinases) and in tyrosine phosphorylation of the receptor itself. Phosphorylation on

FIGURE 7.2. Mitogenic signal transduction pathways and retroviral oncogenes. This figure shows a schematic representation of mitogenic signal transduction. Binding of a growth factor to a growth factor receptor initiates signal transduction pathways involving adaptor proteins, signal transducing proteins, and serine/threonine kinases. This results in the phosphorylation of transcription factors to alter gene expression and execute pro-proliferative or antiapoptotic signals. Components of this pathway that were transduced by acute transforming retroviruses are listed in red.

tyrosine in turn generates specific binding sites for a variety of signaling proteins that contain SH2 (*src* homology region 2) or other protein–protein interaction domains, which themselves may be tyrosine phosphorylated after binding the activated receptor.³⁸⁶ Among the targets of these signaling proteins are intracellular guanine nucleotide exchange factors (GEFs) that activate signal transducing molecules such as p21^{ras}.³⁹ This then initiates a cytoplasmic signaling cascade involving a series of serine/threonine kinases (the mitogen-activated protein [MAP] kinase cascade) that ultimately results in the phosphorylation and activation of nuclear transcription factors, such as AP1 (composed of *jun* and *fos* subunits) and *c-myc*, allowing them to stimulate the expression of various cellular genes.^{34,36,80} Growth factor treatment also activates phosphatidylinositol 3-kinase (PI3K) signaling, which generates antiapoptotic and pro-growth signals mediated by the downstream kinase, *akt*.

A major target of transcriptional activation following growth factor treatment is the cyclin D gene.³⁰⁶ Cyclins, including cyclin D, are regulatory subunits of the cyclin-dependent kinases (cdks), which directly regulate the cell cycle by allowing cells to move past specific cell cycle checkpoints (e.g., the G1/S boundary) (Fig. 7.3). Cyclin concentrations vary periodically throughout the cell cycle, and association of cyclins with cdks stimulates the activity of the cdk complexes, which catalyze the phosphorylation of nuclear substrates. For example, association of cyclin D with cdk4 results in phosphorylation of members of the Rb family (Fig. 7.3). Phosphorylation of Rb proteins causes their release from E2F proteins, a family of transcription factors that was first identified because E2F is required for activation of the adenovirus E2 promoter.²⁶⁸ Rb release increases transcription of a set of E2F-dependent cellular genes that encode proteins required for cellular DNA synthesis, including DNA polymerases, topoisomerases, and

enzymes involved in nucleotide synthesis.¹¹⁴ Thus, growth factor treatment triggers a signal transduction cascade that results in the inactivation of the Rb family and stimulation of the G1 to S phase transition and cellular DNA synthesis.

Cdks are also regulated by the p53 pathway.²⁸⁴ The p53 protein is a transcription factor that can stimulate or repress the expression of various genes. Typically present at low levels

FIGURE 7.3. The cell cycle. The figure shows a simplified version of the cell cycle. The active form of the retinoblastoma family members prevents progression through the G1 phase. Rb-mediated inhibition is abrogated by growth factor treatment, which results in accumulation of cyclin D, stimulation of cyclin-dependent kinases (cdks), and Rb phosphorylation. Rb can also be inhibited by the expression of several DNA virus oncoproteins, such as adenovirus E1A, human papillomavirus (HPV) E7, or simian virus 40 (SV40) large T antigen (see Fig. 7.12).

and inactive, the expression and activity of p53 is induced by a variety of stresses, including DNA damage. An important target of p53-mediated transcriptional activation is p21^{WAF1/CIP1}, an inhibitor of cdk activity and cell cycle progression.¹³⁹ Therefore, a direct consequence of p53 activation is p21^{WAF1/CIP1} induction and the inhibition of cdk activity. This causes the retention of the Rb family in the underphosphorylated form, which inhibits cell cycle progression by preventing E2F-mediated gene activation. Conversely, inhibition of p53 reduces the levels of p21^{WAF1/CIP1}, and the resulting increase in cdk activity and Rb phosphorylation dissociates E2F and Rb, allowing DNA synthesis to occur.

According to this simplified view of cell cycle control, proliferation can be stimulated by activation of mitogenic signaling or by inhibition of tumor suppressor proteins. Not surprisingly, most viral oncogenes function in just this way, either by activating signal transduction cascades or by inhibiting tumor suppressor pathways.^{31,47} Indeed, much of our molecular understanding of mitogenic signal transduction and the role of tumor suppressor proteins in cell proliferation and cancer is derived from genetic and biochemical analysis of viral oncoproteins.

Cells not only respond to mitogenic signals but also possess intrinsic pathways that limit cell proliferation in response to a variety of stresses. DNA damage elicits cell cycle arrest (via p53 activation) to allow cells time to repair the damage. If the damage is extensive, apoptosis will result. Virus infection or oncogene action can also activate checkpoints that block cell proliferation. For example, replicating viral DNA itself can be recognized as foreign and trigger a DNA damage response.⁴⁸⁸ In addition, the aberrant activation of mitogenic signaling pathways by viral oncoproteins can cause unscheduled DNA synthesis, which in turn induces apoptosis or senescence.¹³⁷ Because such premature cell death or inhibition of proliferation will reduce virus yield, these cellular responses can be viewed as antiviral defense mechanisms. In many cases, the p53 and the Rb pathways are required for the execution of these antiviral processes. Neutralization of these tumor suppressor pathways by viral oncoproteins will not only directly stimulate cell proliferation but also interfere with these checkpoints and remove these barriers to transformation and tumorigenesis. Furthermore, when the checkpoint fails, the resulting inaccurate DNA repair or unscheduled DNA synthesis allows the accumulation of mutations in cellular regulatory genes or global genomic instability, which further contribute to the erosion of cell growth control.

TRANSFORMATION BY RETROVIRUSES

Retroviruses were discovered because they caused cancers in animals. The first transmissible tumors associated with retroviruses were avian myeloblastosis in 1908¹⁴³ and avian sarcomas in 1911,³⁸² caused by avian myeloblastosis virus (AMV) and RSV, respectively. Other early retroviruses associated with cancers include murine mammary tumor virus (MMTV, mammary carcinomas)⁶⁰ and murine leukemia viruses (MuLVs, lymphomas and leukemias).¹⁹⁵ Of the seven retrovirus genera, viruses from five (alpha, beta, gamma, delta and epsilon) are associated with cancers. Only lentiviruses and foamy viruses have not been found to directly induce cancer—and for human immunodeficiency virus type 1 (HIV-1), a lentivirus, a major clinical manifestation of acquired immunodeficiency syndrome (AIDS) is development of cancer.

Most oncogenic retroviruses can be divided into two categories, based on the rapidity with which they induce tumors. *Acute transforming* retroviruses induce tumors rapidly (often within weeks in experimental animals) and can often transform cells in culture. As mentioned earlier, acute transforming retroviruses carry additional genetic information beyond the standard genes for retroviral replication (*gag*, *pol*, and *env*; see Chapter 47). These additional sequences, the viral oncogenes, are responsible for rapid and efficient tumorigenesis and cell transformation. *Nonacute* retroviruses induce tumors in animals more slowly, do not carry oncogenes, and usually do not transform cells in culture. Nevertheless, these viruses often induce tumors with high efficiency, typically by causing transcriptional activation of cellular proto-oncogenes.

Acute Transforming Retroviruses and Viral Oncogenes

Acute transforming retroviruses belong to the alpha- and gammaretrovirus genera (Table 7.1). The first acute transforming retroviruses to be studied were avian alpharetroviruses, beginning with RSV and avian acute leukemia viruses such as AMV. Acute transforming gammaretroviruses include murine and rat sarcoma viruses, murine acute leukemia viruses, and feline and simian sarcoma viruses. Study of acute transforming retroviruses and their cognate proto-oncogenes has provided numerous important insights into pathways of growth regulation. Indeed, some of the most important proteins in signal transduction and cancer were first identified through study of retroviral oncogenes, including *Ras*, *Src*, *Abl*, *Myc*, *Fos*, and *Jun*.

RSV and *src*. Infection of chick embryo fibroblasts with RSV results in cell transformation; a focus-formation assay can be used to quantify the amount of transforming virus present.⁴⁶³ After the original isolation of RSV, several different strains of related transforming viruses were developed. Some of these strains (e.g., Schmidt-Ruppin [SR-RSV] and Prague [Pr-RSV]) are replication competent. Others, such as the Bryan high-titer strain, consist of a replication-defective RSV genome, which carries the viral oncogene, as well as a related replication-competent “helper” virus genome (e.g., Rous-associated virus [RAV]). In a mixed infection, this helper virus encodes viral replication proteins *in trans* to allow the production of infectious virus.²⁰⁴

Passage of replication-competent RSV occasionally results in loss of transforming capacity without affecting viral replication—such variants are termed *transformation-defective* RSV (tdRSV).¹³⁰ Thus, oncogenesis and transformation are not required for RSV replication. The size of the tdRSV genome was smaller than wild-type RSV, suggesting that viral genomic sequences responsible for transforming activity were missing from tdRSV. These deleted sequences were mapped to the 3′ end of the RSV genome,⁴⁸⁴ and they were eventually termed *src*,⁸⁶ providing the first example of a retroviral oncogene (Fig. 7.4). *Src* is expressed via a spliced messenger RNA (mRNA) from the splice donor site at the 5′ end of the genome and an acceptor site at the 5′ end of the *src* gene.²⁰²

Antisera from RSV-infected rabbits were used to identify the protein product of the *src* oncogene as a 60-kD phosphoprotein designated pp60^{src}.⁵⁰ When an anti-*src* antibody was incubated with a cell lysate from RSV-transformed cells and

FIGURE 7.4. Structure of Rous sarcoma virus (RSV) and pp60^{src}. The **top part** of the figure shows the proviral structure of avian leukosis virus containing the three retroviral genes required for virus replication, *gag*, *pol*, and *env*. The long terminal repeats (LTRs) are shown in red. The second provirus shows RSV with the *src* gene located at the 3' end of the viral genome. A schematic picture of spliced *v-src* messenger RNA (mRNA) is shown below the RSV provirus, with spliced-out introns depicted as dashed lines. The **bottom part** of the figure shows schematic diagrams of pp60^{v-src} and pp60^{c-src}. Both proteins contain conserved SH2 and SH3 protein-protein interaction domains, tyrosine kinase domains, and an amino-terminal myristal (myr) group. A regulatory tyrosine at position 527 in pp60^{c-src} (Y⁵²⁷) is also shown. pp60^{v-src} contains several amino acid substitutions compared to pp60^{c-src}, represented by the stippling, as well as a frameshift mutation that replaces the 19 carboxyl-residues of pp60^{c-src}, including the Y527, with 12 unrelated amino acids.

γ -³²P-adenosine triphosphate (ATP) as a phosphate donor, ³²P was transferred to the antibody heavy chain, thus identifying pp60^{v-src} as a protein kinase.⁸⁸ Subsequently it was shown that pp60^{v-src} is a tyrosine-specific protein kinase; that is, it phosphorylates tyrosine residues in its substrate proteins.^{89,223} Phosphorylation of proteins on tyrosines is a relatively rare modification (compared to phosphorylation on serine and threonine), and pp60^{v-src} was the first tyrosine kinase discovered. Tyrosine phosphorylation is now known to be a major mechanism to regulate protein activity.

Another key discovery was the determination of the origins of the RSV *src* gene. Hybridization experiments with radioactive *src*-specific DNA probes revealed the presence of homologous sequences in DNA from uninfected chickens.⁴⁴¹ The *src*-specific DNA also hybridized with DNA of other species, and the extent of hybridization correlated with the evolutionary distance from chickens. Thus, the *src* gene of RSV, *v-src*, was derived by capture of a normal cell gene, *c-src*, referred to as a proto-oncogene.

The domains of pp60^{v-src} are shown in Figure 7.4. The protein is modified by myristoylation at the N-terminus, which anchors it to the inner surface of the plasma membrane.⁵² Membrane attachment is necessary for transformation, although not for kinase activity.²⁴³ The kinase domain is located in the internal region of pp60^{v-src}. Two adjacent domains are “*src* homology” domains—SH2 and SH3. These domains were originally identified as regions of homology between *v-src* and *src*-related oncogenes of other avian acute transforming retroviruses.³⁹³ The SH2 and SH3 domains mediate the specific interaction of pp60^{v-src} (and other proteins) with cellular proteins, including regulatory proteins and substrates for phosphorylation.^{261,319} SH2 and SH3 domains are present in many cellular proteins, and they are important

protein-protein interaction motifs. SH2 domains bind phosphotyrosine residues in specific sequence contexts in their target proteins, while SH3 domains bind proline-rich regions.²⁶¹

The *c-src* proto-oncogene encodes a similar protein, pp60^{c-src}, which differs from pp60^{v-src} by several amino acid substitutions throughout the protein and by a different C-terminal sequence due to a frameshift mutation in *v-src* (Fig. 7.4).^{454,460} The C-terminus of pp60^{c-src} is a regulatory domain that contains a crucial tyrosine residue at position 527 (Y⁵²⁷). When Y⁵²⁷ is phosphorylated, it binds the SH2 domain on the same molecule of pp60^{c-src}, resulting in a closed conformation in which the kinase is inactive.⁵⁰³ Dephosphorylation of Y⁵²⁷ displaces the SH2 domain, resulting in activation of *src* kinase.⁹⁴ Of note, the viral protein pp60^{v-src} lacks the regulatory Y⁵²⁷ and is thus constitutively in the open, kinase-active form where it signals for cell transformation by catalyzing high-level phosphorylation of substrates.

Substrates phosphorylated by pp60^{v-src} provide the key to understanding transformation and oncogenesis by RSV. Various substrates have been identified by searching for proteins that show enhanced levels of tyrosine phosphorylation in RSV-transformed cells compared to normal cells.^{91,97,367,381,398,415} pp60^{v-src} substrates whose phosphorylation is important for RSV transformation include the mitogen-activated protein kinase (MAPK) Erk-1/2,³⁸¹ focal adhesion kinase (FAK),³⁹⁸ and Connexin43, a tight junction protein.⁹⁸

Overview of Other Retroviral Oncogenes. The basic principles elucidated by analysis of RSV also apply to the other acute transforming retroviruses and are summarized here. With a few exceptions described below, acute transforming retroviruses contain viral oncogenes resulting from capture of cellular proto-oncogenes (Table 7.3), although the location

TABLE 7.3 Oncogenes Transduced by Acute Transforming Retroviruses

Oncogene	Retrovirus	Oncoprotein ^a	Identity
Growth factor <i>sis</i>	Simian sarcoma virus	p28 ^{env-sis}	Platelet-derived growth factor-B
Receptor tyrosine kinases			
<i>erbB</i>	AEV-ES4, AEV-R, AEV-H	gp65 ^{erbB}	Epidermal growth factor receptor
<i>fms</i>	McDonough FeSV	gp180 ^{gag-fms}	Colony stimulating factor-1 receptor
<i>sea</i>	S13 AEV	gp160 ^{env-sea}	Macrophage-stimulating protein receptor
<i>kit</i>	Hardy-Zuckerman-4 FeSV	gp80 ^{gag-kit}	Stem cell factor receptor
<i>ros</i>	UR2 ASV	p68 ^{gag-ros}	Ligand unknown
<i>eyk</i>	Avian retrovirus RPL30	gp37 ^{eyk}	Gas6 receptor
Cytokine receptor <i>mpl</i>	Mouse myeloproliferative leukemia virus	p31 ^{env-mpl}	Thrombopoietin receptor
Hormone receptor <i>erbA</i>	AEV-ES4, AEV-R	p75 ^{gag-erbA}	Thyroid hormone receptor
Lipid kinase p3k	ASV16	p150 ^{gag-p3k}	Catalytic subunit of PI3K
Ubiquitin ligase <i>cbl</i>	Cas NS-1 MuLV	p100 ^{gag-cbl}	
G proteins			
<i>H-ras</i>	Harvey MSV	p21 ^{H-ras}	
<i>K-ras</i>	Kirsten MSV	p21 ^{K-ras}	
Adaptor protein <i>crk</i>	CT10, ASV-1	p47 ^{gag-crk}	
Nonreceptor tyrosine kinases			
<i>src</i>	Rous sarcoma virus	pp60 ^{src}	
<i>abl</i>	Abelson MuLV	p160 ^{gag-abl}	
<i>fps^b</i>	Fujinami ASV	p130 ^{gag-fps}	
	PRC 11 ASV	p105 ^{gag-fps}	
<i>fes^b</i>	Snyder-Theilen FeSV	p85 ^{gag-fes}

<i>maf</i>	Avian retrovirus AS42	p100 ^{gag-maf}	
<i>ski</i>	SKV ASV	p110 ^{gag-ski-pol}	
<i>qin</i>	ASV31	p90 ^{gag-qin}	

AEV, avian erythroblastoma virus; AMV, avian myeloblastoma virus; ASV, avian sarcoma virus; FeSV, feline sarcoma virus; MSV, murine sarcoma virus; MuLV, murine leukemia virus; NF-κB, nuclear factor-κB; PI3K, phosphatidylinositol 3-kinase.

^aThe nomenclature of viral oncoproteins refer to basic structural data: p, protein; gp, glycoprotein; pp, phosphoprotein; the numbers designate the molecular weight in kilodaltons; the superscript indicates the genes from which the coding information is derived in a 5' to 3' direction.

^b*fps* and *fes* are the same oncogene derived from the avian and feline genomes, respectively.

^c*raf* and *mil* are the same oncogene derived from the murine and avian genomes, respectively.

FIGURE 7.5. Genome maps of avian acute transforming retroviruses. The genome structures of the following avian acute transforming viruses are shown: ALV, avian leukosis virus; MC29, avian myelocytoma virus MC29; AMV-BAI, avian myeloblastosis virus BAI; AEV-ES4, avian erythroblastosis virus ES4. The proviral long terminal repeats (LTRs) are shown in red, and the retroviral structural genes *gag*, *pol*, and *env* are shown in blue, green, and lavender, respectively. Transduced oncogenes are shown in black or gray.

of the oncogene in the viral genome can vary (Fig. 7.5). In some cases the same proto-oncogene has been captured independently by several different viruses. For example, the avian retroviruses Fujinami sarcoma virus and PRC-II both captured the *c-fps* proto-oncogene from the chicken genome, and the Snyder-Theilen strain of feline sarcoma virus captured the homologous gene (*c-fes*) from the cat genome.¹⁹⁴ Proto-oncogene proteins, which generally play positive roles in stimulation of cell growth or division, are typically tightly regulated. The viral oncogene proteins often differ from their parent proteins by amino acid substitutions, deletions, and/or fusion to an intrinsic viral replication protein, most commonly *gag*. These differences lead to activation of the viral oncogene proteins compared to the proto-oncogene proteins by allowing the viral proteins to escape from the tight regulatory control imposed on the normal cellular homologs. For example, deletions may lead to loss of regulatory regions present in the normal proto-oncogene protein (e.g., pp60^{v-src} vs. pp60^{c-src} as described earlier). Amino acid substitutions can also result in loss of regulatory mechanisms (e.g., the *v-ras* proteins), and fusion of viral sequences to the oncogene protein can enhance activity (e.g., the *v-abl* protein). In other cases, the viral oncogene product may be identical to the proto-oncogene product but delivers a sustained or enhanced signal because it is overexpressed. In either case, the viral oncogene proteins signal for cell proliferation by the same molecular mechanisms as the proto-oncogene proteins, but in a constitutive or uncontrolled manner (see Fig. 7.2).

Most acute transforming retroviral genomes are replication defective, because capture of the proto-oncogene sequences generally results in loss of part of the viral genome (Fig. 7.5). Therefore, in order to produce infectious virus, these viruses require co-infection with a helper virus that supplies replication functions. Infection of cells with low concentrations of an acute transforming virus stock can generate foci of transformed cells harboring only the acute transforming viral genome (and not the helper virus genome). Cells from these foci express the viral oncogene, but they do not produce infectious virus—they are called nonproducer cells. Infectious transforming virus can be recovered from these nonproducer cells by infecting them

with a replication-competent helper virus to provide replication functions.

Retroviral oncogenes also differ from their corresponding proto-oncogenes because they lack introns. This likely reflects the mechanism of oncogene capture, which is thought to be initiated by integration of a retroviral provirus upstream from a cellular proto-oncogene.⁴⁵⁴ Read-through transcription from the retrovirus into the proto-oncogene causes the production of a fusion transcript containing 5' retroviral sequences and 3' proto-oncogene sequences. The fusion transcript is then processed by mRNA splicing to remove the proto-oncogene introns, followed by packaging into virions. In a subsequent infection, recombination during reverse transcription presumably results in recovery of the 3' end of the viral genome and the generation of an acute transforming retroviral genome containing a captured oncogene lacking introns.

Mechanism of Action of Retroviral Cytoplasmic and Membrane-Associated Oncogene Products (see Fig. 7.2).

Many oncogenes encode membrane-associated proteins that are derived from RTKs and other growth factor receptors. For example, the *v-erbB* oncogene of AEV ES4 is a transduced version of the EGF receptor.¹²⁵ In comparison to the wild-type EGF receptor, the *v-erbB* protein of AEV lacks the extracellular growth factor binding domain, as well as a tyrosine-containing inhibitory autoregulatory domain at the C-terminus (analogous to Y⁵²⁷ of pp60^{c-src}).²¹⁰ As a result, the truncated *v-erbB* protein delivers downstream signals in an EGF-independent manner. Other RTKs captured and constitutively activated by acute transforming retroviruses include the stem cell factor receptor (*v-kit*) and the colony-stimulating factor 1 receptor (*v-fms*).^{219,425,517} The *v-mpl* oncogene encodes a constitutively active version of the thrombopoietin receptor, which lacks intrinsic kinase activity but associates with intracellular tyrosine kinases.^{109,249,291} The *v-cbl* oncogene encodes a ubiquitin ligase that can regulate receptor abundance and activity.²³⁹ On the other hand, the *v-sis* oncogene of simian sarcoma virus is a transduced version of a growth factor itself, the platelet-derived growth factor B chain (PDGF-B) gene.^{79,338} Thus, *v-sis* can transform only cells that express the PDGF receptor.

FIGURE 7.6. The ras cycle. Cellular ras proteins exist in two different forms, active guanosine triphosphate (GTP)-bound ras (green) and inactive GDP-bound ras (red). Inactive ras is activated by guanine nucleotide exchange factors (GEFs, such as SOS) that load GTP onto ras; GEFs are activated by growth factor receptor signaling. Active ras is inactivated by its intrinsic GTPase activity, which hydrolyzes bound GTP to guanosine diphosphate (GDP). GTPase activity is stimulated by GTPase activating proteins (GAPs). Activating point mutations at particular positions in v-ras cause the accumulation of ras in the active form, usually by preventing GAP action. Active ras induces signaling by binding and activating effector proteins such as raf.

The *src* family constitutes a class of membrane-associated tyrosine kinases that function in the cytoplasm and lack a ligand binding domain. Thus, *src* family members are not RTKs. In addition to *v-src* itself, other avian acute transforming retroviruses contain the *v-fps/v-fes* oncogene and the *v-yes* oncogene.¹⁹⁴ These oncogene proteins share substantial homology with pp60^{v-src} in the kinase domain as well as in other domains.^{261,393} There are other cellular tyrosine protein kinases in the *src* family that function in different signal transduction pathways (e.g., *lck*, whose protein is important for signaling in B lymphocytes⁴⁷⁸), but they have not been captured by acute transforming retroviruses. The genes encoding other cytoplasmic tyrosine kinases unrelated to *src* have been transduced and activated by other acute transforming retroviruses, such as the *v-abl* oncogene of Abelson murine leukemia virus.^{496,497}

The cytoplasmic products of other retroviral oncogenes are kinases that phosphorylate protein substrates on serines or threonines, rather than tyrosines. Three oncogenes in this class are *v-raf* (of murine sarcoma virus 3611 [and the homologous *v-mil* from an avian virus]),^{234,372} *v-mos* (of Moloney murine sarcoma virus),⁴¹³ and *v-akt* (of Akt murine leukemia virus).²⁴ The corresponding cellular proto-oncogene proteins function in different signaling pathways. Cellular Raf protein is a mediator in signal transduction from RTKs and Ras (see later), initiating a cascade of protein phosphorylations that ultimately leads to phosphorylation and nuclear translocation of MAPKs of the extracellular signal-regulated kinase (ERK) family.^{262,514} Cellular Mos protein is required for meiosis and is a component of cytoskeletal factor (CSF).⁵⁰⁸ *v-mos* is activated primarily by overexpression from the viral long terminal repeat (LTR).³³ Cellular Akt protein is a key intermediate in downstream signaling from PI3 kinase, which is also coupled to RTK signaling (see Fig. 7.2). Akt activation delivers survival and proliferative signals to cells. In addition, PI3 kinase itself has been captured by an avian acute transforming retrovirus (AS-16) as the *v-p3k* oncogene.⁶⁴ For the viral oncogenes that encode protein kinases, constitutive, unregulated enzyme activity causes over-

active signaling through the corresponding signal transduction pathways, leading to transformation and tumorigenesis.

Other important cytoplasmic oncogenes are the *ras* oncogenes, *v-Hras* and *v-Kras*, identified in Harvey and Kirsten murine sarcoma viruses, respectively.^{86,145} These viruses were generated by the capture of two closely related cellular proto-oncogenes, *c-Hras* and *c-Kras*, when MuLVs were passaged through rats. The cellular Hras and Kras proteins, which play critical roles in signal transduction, are guanosine triphosphatases (GTPases) (known as G proteins) that bind guanine nucleotides (guanosine diphosphate [GDP] or guanosine triphosphate [GTP]). In the GTP-bound form, Ras proteins induce signals that result in cell proliferation (e.g., by binding and activating Raf kinase), but they are inactive when bound to GDP (Fig. 7.6).^{39,44} Guanine nucleotide exchange factors (GEFs), which stimulate replacement of GDP with GTP, cause inactive Ras to cycle to GTP-bound, active Ras. GEFs include adaptor proteins such as Grb-2 or Sos, which are mobilized by RTK activation.^{136,292} The active GTP-bound Ras cycles back to the inactive form by hydrolysis of the bound GTP to GDP by the intrinsic GTPase activity of the Ras protein, which is stimulated by GTPase activating proteins (GAPs).³⁵ The *v-Hras* and *v-Kras* proteins contain missense mutations at key residues (e.g., amino acids 12 and 59 for *v-Hras*)⁴⁵⁹ that reduce the ability of GAP to stimulate GTP hydrolysis.¹ Therefore, the *v-Ras* proteins accumulate in the active, GTP-bound form because they are unable to cycle to the inactive form, and they signal constitutively for cell growth.

The avian sarcoma virus CT10 and its transduced oncogene, *v-crk*,³⁰⁷ have provided insight into a family of cellular proteins known as adaptor proteins. The proto-oncogene protein *c-crk* (*crkI*), along with proteins from related proto-oncogenes *crkII* and *crkL*, contain SH2 and SH3 domains, but they do not have enzymatic activity. Rather, they function as adaptor proteins that assemble proteins into signal transduction complexes by way of interactions via the SH2 and SH3 domains. Cellular signaling proteins that interact with Crk family proteins include Abl, Sos, and FAK.³⁰⁴

Mechanism of Action of Retroviral Nuclear Oncogene Products (see Fig. 7.2). The nuclear oncogenes of retroviruses are largely derived from proto-oncogenes that encode DNA binding proteins, many of which act as transcription factors. The *v-myc* oncogene, originally identified in the avian acute leukemia virus MC29 (but also captured by other avian acute transforming viruses), was one of the first studied.^{421,476} The *c-myc* protein (Myc) is involved in early responses to mitogenic stimuli and binds E-box motifs in promoters/enhancers of target genes.¹³⁸ Myc exists as a homodimer or as a heterodimer with a related protein, Max. The Myc-Myc homodimers bind E-boxes with low affinity, while Myc-Max heterodimers bind with high affinity.³² Early after a mitogenic stimulus, levels of Myc transiently rise, leading to activation of E-box-containing genes such as those encoding E2F and cyclin D and repression of genes including those encoding cdk inhibitors.¹³⁸ *v-myc* appears to transform cells because of its constitutive overexpression of the retroviral LTR.

The *v-myb* oncogene was also discovered in two different avian acute leukemia viruses (AMV BAI A and AMV E26).²⁵⁸ It is derived from *c-myb*, which encodes a cellular DNA binding protein that acts as a transcription factor important in hematopoietic cell development.²⁸ Structural alterations in *v-myb* appear to be responsible for activation.^{28,193}

The oncogene of acute transforming viruses of the Finkel-Biskis-Jenkins (FBJ) murine osteosarcoma virus complex is *v-fos*,⁴⁷² and *v-jun* is the oncogene of avian sarcoma virus S17 (“jun” is 17 in Japanese).²⁹⁷ The *c-fos* and *c-jun* proto-oncogenes encode nuclear DNA binding proteins that are subunits of the transcription factor, activator protein-1 (AP1).³⁷⁵ Jun can homodimerize, or it can heterodimerize with Fos. Jun-Jun homodimers bind AP1 sites in DNA with low affinity, while Fos-Jun heterodimers bind these sites with high affinity. Activation of Fos transcription from undetectable levels is one of the earliest events after mitogenic stimulation—levels of Fos protein rise within 15 minutes of bombesin stimulation in fibroblasts.³²⁴ In contrast, Jun protein is present in the absence of mitogenic stimulation, and Jun levels do not change substantially in response to growth factor treatment. As a result, early after mitogenic stimulation, there is a shift from Jun-Jun homodimers to Fos-Jun heterodimers, resulting in activation of promoters/enhancers containing AP1 sites.³²⁹ Expression of these target genes (e.g., *c-myc*)²²⁷ is important for cell division and growth. Both the *v-jun* and the *v-fos* proteins contain structural alterations responsible for oncogenic activation. For example, *v-jun* contains missense mutations and a deletion that removes an auto-inhibitory segment, resulting in constitutive activation.⁴¹

Another nuclear oncogene is *v-erbA* of AEV. The *c-erbA* proto-oncogene encodes the thyroid hormone receptor- α (THR- α), a sequence-specific DNA binding protein.^{395,487} In contrast to wild-type THR- α , which binds DNA and activates transcription of target genes, the *v-erbA* protein consists largely of the DNA binding domain.^{105,395} As a result, it binds to DNA nonproductively and acts as a dominant negative form by inhibiting transcription of THR- α -responsive genes. This leads to a block in erythroid cell differentiation, which in turn results in enhanced proliferation of undifferentiated erythroid progenitors.

The *v-rel* oncogene was initially identified in avian reticuloendotheliosis virus.^{73,443} The *c-rel* proto-oncogene encodes

a member of the nuclear factor- κ B (NF κ B) transcription factor family and is important for B-cell development.¹⁸⁰ C-Rel can homodimerize or heterodimerize with the p50 NF κ B protein and bind NF κ B sites in target genes. Point mutations and amino acids derived from env are required for v-rel activation.^{172,457}

Tumorigenesis by Nonacute Retroviruses

Oncogenic nonacute retroviruses belong to the alpha-, beta-, and gammaretrovirus genera. Prototypic nonacute retroviruses include avian leukosis virus (ALV), MMTV, and various MuLVs. These viruses are replication competent, lack viral oncogenes, and do not transform cultured cells. In contrast to tumors induced by acute transforming retroviruses, which are often polyclonal, tumors induced by nonacute retroviruses are monoclonal or oligoclonal (i.e., derived from one or a few transformed cells). Another feature of these viruses is that high-level infection in animals typically occurs many months before development of tumors. Thus, infection is not synonymous with oncogenic transformation for nonacute viruses. The common mechanism by which most nonacute retroviruses induce tumors is insertional activation of cellular proto-oncogenes by the integrated retroviral genome.

B Lymphomas Induced by ALV and Activation of *c-myc*.

Pioneering experiments investigating tumorigenesis by nonacute retroviruses were conducted on chicken B-cell lymphomas induced by ALV. Neel et al³³¹ analyzed DNA from these tumors and found that many of them did not contain intact integrated ALV proviruses, although each tumor contained at least some segment of viral DNA. They studied tumor RNA by northern blot analysis by using two different radioactive viral cDNA hybridization probes, one representing the entire viral coding region and another representing only the ends of the viral RNA including portions of the viral LTR. The full-length probe did not detect viral RNAs in all tumors; however, the LTR probe invariably detected transcripts in tumors, and different tumors gave transcripts of similar sizes. This led Neel et al³³¹ to propose the *promoter insertion* model of ALV tumorigenesis, in which transcription from the downstream ALV LTR continues into adjacent cellular sequences (Fig. 7.7). Furthermore, the similar sizes of the transcripts suggested that the ALV proviruses were inserted into the same chromosomal locus in different tumors. Further experiments showed that the ALV LTR was indeed inserted into the same chromosomal region in independent tumors, adjacent to the *c-myc* proto-oncogene.²¹¹ This placed *c-myc* under control of the strong ALV promoter/enhancer, resulting in read-through transcription into the proto-oncogene. Thus, *c-myc* can be activated either by transduction by the acute transforming retroviruses or by proviral insertion by the nonacute retroviruses. Many ALV-induced tumors contain a deletion of a portion of integrated proviral ALV DNA, resulting in loss of the upstream LTR, so that most of the viral DNA is not transcribed. Deletion of the upstream LTR likely stimulates the activity of the downstream LTR, which drives enhanced transcription of *c-myc*.

In some ALV-induced B lymphomas overexpressing *c-myc*, the relative transcriptional orientations of ALV DNA and *c-myc* were not consistent with the promoter insertion model.³⁵² For example, some tumors contained proviral DNA

FIGURE 7.7. Insertional activation of cellular proto-oncogenes by retroviruses. The **top two diagrams** show proto-oncogene activation by promoter insertion. The **top diagram** shows a provirus integrated upstream of a proto-oncogene in the same transcriptional orientation. The thickness of the horizontal arrows indicates the relative level of expression. Partial deletion of the provirus activates the downstream long terminal repeat (LTR), which results in read-through transcription into the proto-oncogene. The **third diagram** shows proto-oncogene activation by enhancer activation. In the example shown, the provirus integrates farther upstream from the proto-oncogene in the opposite transcriptional orientation, and the enhancer in the viral LTR activates expression from the proto-oncogene promoter (dashed arrow). Proviruses inserted downstream of a proto-oncogene can also enhance expression. The **bottom three diagrams** show a proto-oncogene with four exons. Proviral insertion in the same transcriptional orientation in the 3' portion of the proto-oncogene could result in synthesis of a C-terminally truncated protein product due to cleavage/polyadenylation sequences in the LTR. A provirus inserted in the 5' portion of the proto-oncogene could be transcribed into downstream proto-oncogene exons followed by splicing from a viral splice donor site to a proto-oncogene splice acceptor site. This could result in the deletion or splicing out of proto-oncogene exons and expression of an N-terminally truncated protein product. If the deleted portions regulate the activity of the wild-type protein, these deletions might result in proto-oncogene activation.

inserted upstream of *c-myc* but in the opposite orientation, whereas in other cases the provirus was inserted downstream of *c-myc* (Fig. 7.7). Activation of *c-myc* expression in these cases can be explained by activation of the endogenous *c-myc* promoter by the enhancer sequences in the ALV LTR, which can activate adjacent promoters in an orientation- and position-independent manner. Thus, activation of proto-oncogenes by nonacute retroviruses can be considered as LTR activation, either by promoter insertion or by enhancer activation. Insertional activation of proto-oncogenes has proven to be a common mechanism of tumorigenesis by nonacute retroviruses. Other variations of these mechanisms are described in the next sections.

MMTV Tumorigenesis. MMTV (a betaretrovirus) also employs insertional activation. Common proviral insertion sites (CISs) were identified³⁴⁰ in independently arising MMTV-induced mammary tumors. For MMTV, the first CIS did not correspond to any proto-oncogene known at the time, but by analogy to ALV-induced B lymphomas, it was hypothesized that the CIS marked a cellular gene that was activated by the MMTV provirus. This gene was named *int-1*

(integration site-1), and *int-1* RNA was overexpressed in tumors. Subsequently *int-1* was renamed *wnt-1* because the *Drosophila* homolog had been identified by the developmental mutation *wingless*.³⁷⁸ *Wnt-1* is an important molecule in the *Wnt*- β -catenin signal transduction pathway, which is mutated in a wide variety of human cancers, most notably colorectal cancer.²⁵⁴ Thus, CISs initially identified in nonacute retroviral tumors led to discovery of new proto-oncogenes (Table 7.4). In contrast to ALV-induced B lymphomas where the provirus was integrated quite near *c-myc*, the MMTV provirus in most cases was inserted farther from *Wnt-1*.³⁴⁰ Activation of *Wnt-1* likely occurs by enhancer activation, because transcriptional enhancers can work over relatively long distances (kilobases). Other CISs in MMTV-induced tumors include *int-2* (FGF-3),¹²⁰ *int-3*, and *int-4*.²⁴⁷

MuLV Leukemogenesis. MuLVs are gammaretroviruses and include Moloney MuLV (M-MuLV), SL3-3 MuLV, and radiation leukemia virus (RadLV), which induce T lymphoma, and Friend MuLV (F-MuLV), which induces erythroid or myeloid leukemia. Activation of *c-myc* commonly occurs in leukemias induced by M-MuLV.^{417,440} Other M-MuLV

MuLV, murine leukemia virus; RadLV, radiation leukemia virus.

Data from retroviral tagging of mice genetically predisposed to cancer (e.g., *myc* transgenic mice) are not included here. They can be found in the Mouse Retrovirus Tagged Cancer Gene (RTCG) database at <http://RTCGD.ncifcrf.gov>.

^aInsertions associated with tumor progression or that collaborate with other proto-oncogene activations.

^bAlso contains v-abl oncogene.

^cCommon proviral insertion site of helper virus.

^dAlso contains gp55 oncogene.

^eInsertion at *p53* inactivates its function.

tumors contained novel CISs that led to the discovery of new proto-oncogenes such as the cytoplasmic serine/threonine protein kinases, *pim-1* and *pim-2*^{48,99} (Table 7.4). A number of other CISs have been identified in T lymphomas induced by M-MuLV or RadLV, some of which correspond to known cellular genes such as cyclin D2.²⁰⁵ F-MuLV-induced tumors show activation of a different set of proto-oncogenes than those activated by M-MuLV. Proto-oncogenes commonly activated by F-MuLV include *fli-1* (a nuclear DNA binding protein of the *ets* family), *fim-1*,⁴³⁵ and *fim-2* (M-CSF).¹⁸² In rapidly arising erythroid leukemias induced by the Friend virus complex, a provirus activates the *spi-1* proto-oncogene, which encodes another *ets* family transcription factor.^{320,350} In addition, an acute transforming retrovirus has also been identified in the Friend virus complex: spleen focus-forming virus (SFFV), which contains an oncogene encoding gp55. Gp55 is unusual in that it is not derived from a cellular proto-oncogene, but rather is a deleted form of an endogenous (genetically transmitted) MuLV *env* gene that recombined into the F-MuLV genome.⁴⁹⁸

The different activated proto-oncogenes in leukemias induced by M-MuLV and F-MuLV likely reflect the fact that different signaling pathways are important for transformation of lymphoid versus erythroid/myeloid cells. Studies of MuLV leukemogenesis revealed that the viral LTRs played critical roles in leukemogenicity. First, exchange of the U3 regions of the LTRs between an oncogenic MuLV (e.g., M-MuLV or SL3-3) and a nononcogenic virus (e.g., an endogenous MuLV) demonstrated that leukemogenicity was lost when the U3 region of the LTR was derived from the nononcogenic MuLV.^{118,281}

Furthermore, substitution of the enhancer region of the F-MuLV LTR into M-MuLV shifted the disease spectrum from T-lymphoid to erythroid/myeloid tumors.⁶⁸ This finding reflects the fact that enhancers are often tissue specific; that is, they specifically bind transcription factors present in a subset of differentiated cells. Indeed, in reporter assays, the M-MuLV LTR is most active in T-lymphoid cell lines and less so in erythroid/myeloid cells, while F-MuLV LTR is most active in erythroid/myeloid cells.⁴²⁸ Taken together, these results indicate that in order for an MuLV to induce tumors, it must have LTRs that efficiently activate cellular proto-oncogenes in the target cells.

Recombinant inbred strains of mice have also been used to study MuLV leukemogenesis. Certain strains of mice genetically transmit replication-competent endogenous MuLVs to their offspring. Crossing such strains with other mouse strains, followed by in-crossing, yields recombinant inbred lines. Some of these lines have high rates of leukemia development due to activation of the endogenous virus, which in turn infects cells and activates cellular proto-oncogenes. Leukemias in such lines have been used to identify new proto-oncogenes that are activated in the tumors, such as *evi-1* (endogenous virus insertion site-1) and *evi-2*, associated with myeloid leukemias.⁹²

Another feature of leukemogenesis by MuLVs is the formation of recombinants between these viruses and endogenous MuLV proviruses present in the mouse germline. The genomes of most higher eukaryotes carry retroviral DNA that was introduced by germline infection by retroviruses sometime during evolution. This endogenous retroviral DNA is transmitted vertically from parents to offspring, and multiple endogenous proviruses have accumulated over time. Indeed, approximately 8%

of the human genome is derived from endogenous retroviruses. Many endogenous retroviruses are replication defective, perhaps reflecting evolutionary selection against genetically transmitted, replication-competent viruses, but some can still be expressed. When mice are infected with MuLVs, recombination between the incoming MuLV and endogenous MuLVs can occur to generate mink cell focus-inducing (MCF) recombinant viruses.²⁰⁷ MCFs express an endogenous MuLV-derived envelope protein that allows them to infect cells by using a different cellular receptor than the original MuLV. Most MuLVs that infect mice or mouse cells are ecotropic and bind to the ecotropic receptor murine cationic amino acid transporter 1 (MCAT-1) on mouse cells; in contrast, MCFs infect via the xenotropic and polytropic retrovirus receptor (XPR-1) receptor. MCFs have been suggested to be the *proximal leukemogens* for some MuLVs (e.g., in AKR mice that develop spontaneous leukemia by activation of an ecotropic endogenous MuLV [Akv-MuLV]),²⁰⁷ although for other MuLVs MCF recombinants may play early roles in disease.¹⁴⁸ For MuLVs with weak LTR enhancer activity (e.g., Akv-MuLV), MCF recombinants also acquire a stronger LTR by recombination with a second endogenous provirus.⁴⁴⁸

Other Mechanisms of Insertional Oncogenesis. While the predominant mechanisms of oncogenesis by nonacute retroviruses are LTR-mediated activation of proto-oncogenes by promoter insertion or enhancer activation, several related mechanisms have also been identified, all of which involve integration of proviral DNA into the genome at specific places, leading to changes in cellular gene expression and development of tumors.

In one such mechanism, a provirus is inserted upstream of a proto-oncogene or within a proto-oncogene in the same transcriptional orientation as the cellular gene. The viral genome is transcribed beginning in the upstream LTR, but transcription continues past the poly(A) signal in the downstream LTR into the proto-oncogene (Fig. 7.7). Splicing of the fusion transcript from the viral splice donor into downstream proto-oncogene splice acceptor sites can generate mRNAs that encode truncated proto-oncogene proteins. This has been observed in erythroid leukemias induced by ALV in line 15₁ chickens, where a truncated c-ErbB (EGF receptor) protein is produced,¹⁶⁴ and in myeloid leukemias induced by M-MuLV in pristane-primed Balb/c mice, where a truncated c-Myb protein is generated.³³⁰ Similarly, transcription of a proto-oncogene could terminate at the LTR of a provirus inserted into a downstream portion of the proto-oncogene, resulting in a C-terminal truncation (Fig. 7.7). In these cases, the truncations remove regulatory domains from the proto-oncogene proteins, leading to the synthesis of unregulated, growth stimulatory proteins.

As mentioned earlier, inoculation of chicken embryos with ALV leads to rapid development of B lymphomas harboring proviral activation of *c-myc*. In addition, some ALV-induced lymphomas contain proviruses at both *c-myc* and a novel CIS, *bic-1*.⁸⁴ Although *bic-1* RNA was overexpressed in these tumors, presumably due to provirus insertion, *bic-1* does not contain protein-coding sequences. Rather, *bic-1* encodes the precursor for microRNA (miRNA) miR155—a so-called onco-miR that is overexpressed in a variety of human cancers.¹⁴⁹ miR155 causes the down-regulation of growth inhibitory genes, which presumably accounts for its oncogenic potential.³⁸ Insertional activation of other miRNAs has also been observed in retrovi-

rally induced tumors. The miR-103-363 cluster is activated in RadLV-induced T lymphomas,²⁷⁵ and miR-106 a is activated in SL3-3 MuLV-induced T lymphomas.²⁹³

Another mechanism of insertional oncogenesis involving miRNAs has been described for T lymphomas induced by SL3-3 MuLV. In these tumors, the provirus is inserted into downstream noncoding sequences of the *gfi-1* proto-oncogene.¹⁰⁰ These sequences contain binding sites for several miRNAs, including miRNA-155. This results in overexpression of a truncated *gfi-1* mRNA, presumably because the inserted provirus eliminates binding sites for inhibitory miRNAs.

Finally, insertions of the SFFV provirus into the p53 tumor suppressor gene occur in erythroleukemia cell lines established from tumors induced by the acute transforming Friend SFFV/F-MuLV complex.^{25,323} The insertions inactivate p53, and in these tumors the normal *p53* gene is generally lost. Similarly, in BXH2 recombinant inbred mice, proviral insertion occurs in *evi-2*, which encodes the NF-1 tumor suppressor.²⁷⁷ In these cases, then, rather than activating proto-oncogenes, proviral insertion inactivates tumor suppressor genes.

Multiple Changes in Nonacute Retrovirus-Induced Tumors.

Multiple genetic changes may be involved in some tumors induced by nonacute retroviruses. Proviral insertions next to more than one proto-oncogene have been observed in some MMTV-induced mammary tumors and M-MuLV-induced T lymphomas (e.g., *wnt-1* and *int-2* for MMTV and *c-myc* and *pim-1* for M-MuLV).^{311,417} Although in some cases this reflects two independent tumors, each containing an insertion event near a different proto-oncogene, in other cases the same tumor cell harbors both of the activated proto-oncogenes, suggesting that the proto-oncogenes cooperate in tumorigenesis. This notion has been further developed by studying leukemogenesis in transgenic mice. For example, mice with a *pim-1* transgene under expression of a T-cell-specific promoter develop lymphomas very inefficiently. However, if these mice are infected with M-MuLV, tumors develop extremely rapidly, and analysis of the tumors revealed proviral activations of both *c-myc* and *n-myc*.⁴⁷³ This result provided direct evidence that overexpressed *pim* family members and *myc* family members can cooperate in T lymphomagenesis. In later experiments, several additional pairs of cooperating proto-oncogenes have been identified.⁴⁷⁴

Secondary events may also be important in tumors induced by acute transforming retroviruses. Abelson MuLV (carrying the *v-abl* gene) induces B-cell lymphomas when it is co-infected with an M-MuLV helper virus but not with other helper MuLVs, suggesting that M-MuLV also contributes to tumor development. The critical region for this activity was localized to the M-MuLV LTR, and a CIS for the M-MuLV helper in Abelson MuLV tumors was identified adjacent to the *ahi-1* gene.³⁶¹ Thus, expression of the *v-abl* oncogene along with *ahi-1* protein²³⁸ is required for efficient lymphomagenesis.

Another approach to identify activated proto-oncogenes that contribute to later steps in tumorigenesis involves *in vitro* or *in vivo* passage of tumors. For example, *in vitro* passage of rat T lymphomas induced by M-MuLV results in acquisition of additional proviral CISs, which have been termed tumor progression loci (e.g., *tpl-1* and *tpl-2*).^{20,349} Likewise, *in vitro* infection of growth factor-dependent M-MuLV-induced

FIGURE 7.8. Proto-oncogene activation in nonviral tumors. The figure shows three mechanisms of proto-oncogene activation in tumors of nonviral origin: tandem amplification of the oncogene and flanking cellular DNA, resulting in overexpression of the oncogene; chromosomal translocation resulting in overexpression and/or structural alteration of the oncogene, leading to its constitutive activation; and point mutations in the coding region of an oncogene, resulting in constitutive activation. The thickness of the horizontal arrows indicates the relative level of expression. Black, proto-oncogene; blue, flanking normal cell DNA; yellow, translocated chromosome. Red X indicates mutation.

lymphomas with a second MuLV (MCF-MuLV) resulted in the generation of factor-independent cells, which contained proviral activation of new proto-oncogenes (e.g., *gfi-1*).^{159,179} Finally, as described earlier, insertional inactivation of p53 occurs during *in vitro* passage of erythroleukemia cell lines from Friend virus complex-infected mice, so it is a late step in the development of these lines.²⁵

Proto-Oncogene Discovery in the Age of Genomics. The initial discovery of CISs and activated proto-oncogenes was very labor intensive and typically required identifying virus-induced tumors harboring a small number of proviruses, followed by generating a lambda phage library of tumor DNA and cloning all of the proviruses. Adjacent cell sequences from each provirus were then used as hybridization probes on Southern blots of DNA from other virus-induced tumors to identify additional tumors that harbored proviral insertions in the same cellular site.^{211,352} The availability of whole genome sequences substantially increased the pace of CIS discovery, particularly in mice.⁴²² New cloning techniques such as inverse polymerase chain reaction (PCR) facilitated the cloning of proviral DNA and viral–host junctions.⁴²² Sequencing of the adjacent cellular DNA in these clones, followed by alignment of the cellular DNA sequence with the host genome, allowed rapid localization of each proviral insertion site within host cell DNA. Common insertion sites could be readily identified by insertions into similar chromosomal locations in different tumors.

The advent of high-throughput DNA sequencing has further enhanced the efficiency of CIS discovery. In a recent approach, linker-ligated PCR techniques are used to amplify viral–cellular junctions from tumor samples, and then the entire reactions are analyzed by deep sequencing.²⁶⁵ This provides high-resolution analysis of all of the proviral insertions in a tumor, and then comparison with other tumors induced by the same virus is used to identify CISs. In a recently published study, over 9,000 insertion sites were analyzed in a collection of 476 murine tumors, and multiple new CISs were identified.²⁶⁵

Activation of Proto-Oncogenes in Nonviral Tumors

Studies of retroviral oncogenes and their corresponding proto-oncogenes led to the first discoveries of molecular genetic alterations in human cancers, namely, activation of proto-oncogenes. Genetic alterations in cancer are now major subjects of study in cancer research. The basic mechanisms of proto-oncogene activation in tumor cells—gene amplification, chromosomal translocation, and missense mutations—mirror the consequences of retroviral activation of oncogenes (Fig. 7.8).

Gene amplification in tumor cells is manifested by tandem head-to-tail duplication of chromosomal regions (up to several hundred kilobases in length), resulting in as many as ~10 additional copies of the amplified region of the chromosome. Amplified regions typically contain a proto-oncogene (as well as flanking genes) and were originally detected on Southern blots by cross-hybridization with viral oncogene probes. For example, *c-myc* is amplified in several kinds of tumors such as lung cancer and neuroblastoma.^{410,411} Amplification leads to overexpression of the protein product of the proto-oncogene and excessive stimulation of growth. Early studies on *c-myc* amplification led to the discovery of *c-myc*–related genes that were also amplified in tumors (e.g., *n-myc* in neuroblastomas and *l-myc* in lung cancers). These findings expanded the concept of proto-oncogenes beyond those that had been captured by acute transforming viruses: proto-oncogenes are cellular genes that are activated in tumors and stimulate growth or division.

Chromosomal translocations have also been observed in tumors; for example, the 9:22 translocation (the Philadelphia chromosome) is pathognomonic for chronic myelogenous leukemia (CML).³⁸⁵ The first molecular description of such translocations was in Burkitt lymphoma (of B-cell origin), where *c-myc* is characteristically present at an 8:14 translocation breakpoint,¹⁰³ which moves *c-myc* on chromosome 8 next to the immunoglobulin heavy chain gene. In other cases, Burkitt lymphoma cells harbor a translocation of the *c-myc* gene into the immunoglobulin light chain locus on chromosome 22. In B lymphocytes, whose function is to produce antibodies, the immunoglobulin genes are highly expressed. Therefore, translocation

of *c-myc* into these regions leads to *c-myc* overexpression and growth stimulation. Similarly, the 9:22 translocation in CML juxtaposed *c-abl* from chromosome 9 next to the Bcr (breakpoint cluster region) on chromosome 22.¹⁰⁸ This translocation results in a novel Bcr-abl fusion protein, which exhibits elevated tyrosine kinase activity compared to the normal Abl protein.²⁶⁴ Thus, chromosomal translocations can have the same consequences as proviral insertion and proto-oncogene transduction. Characteristic translocations have been detected in various additional tumors (particularly of hematopoietic lineage, but also in prostate and lung carcinoma), and genes at the translocation junctions either are overexpressed or have altered signaling properties.²⁵⁷ These genes are now considered proto-oncogenes as well.

Missense mutations in proto-oncogenes in tumors were first detected by DNA transfection experiments. When naked DNA from certain tumor cell lines or primary tumors was introduced into mouse NIH-3T3 fibroblasts, foci of transformed cells appeared, whereas DNA from normal cells was, in general, devoid of transforming activity.⁴²⁶ Thus, these tumor cells contained a genetic change that could be transferred to other cells to cause transformation. Molecular cloning from the EJ bladder carcinoma cell line identified the transforming gene as cellular *H-ras*.³⁴⁶ The *H-ras* gene in the EJ cells had a missense mutation at residue 12 (G12V) of the protein,⁴⁵⁸ resulting in inhibition of GTPase activity and constitutive signaling, similar to changes in the *v-ras* proteins described earlier. Other tumors had missense mutations in the *K-ras* gene¹¹⁷ or in a third homolog, *N-ras*.¹⁶⁸ *Ras* mutations are some of the most frequent genetic alterations in human tumors (e.g., they are present in greater than 90% of pancreatic cancers), but this assay has identified other transforming genes in human tumor DNA as well. Activating mutations have also been found by direct sequencing of cellular proto-oncogenes (e.g., EGF receptor mutations in lung cancer, c-kit mutations in gastrointestinal stromal tumors, and B-raf mutations in melanoma).

Other Mechanisms of Retroviral Oncogenesis

While transduction of oncogenes by acute transforming retroviruses and insertional activation of proto-oncogenes by nonacute retroviruses are the most common mechanisms of retroviral oncogenesis, a few retroviruses induce tumors by other mechanisms. These mechanisms involve replication-competent retroviruses, which carry genes that function as oncogenes, although they are not derived from cellular genes.

HTLV-I and BLV. Human T-cell leukemia virus type I (HTLV-I) and bovine leukemia virus (BLV) induce adult T-cell leukemia (ATL) in humans and bovine B-cell leukemia, respectively. These deltaretroviruses are covered in Chapter 48 in detail. *In vitro* infection of T lymphocytes with HTLV-I leads to immortalization, suggesting that the virus carries an oncogene.²⁴⁵ Deltaretroviruses contain additional genes not found in other retroviruses, which encode regulatory proteins such as Tax, encoded by alternatively spliced mRNA within the *X* region of the virus, downstream of *env*. The Tax protein is a transcriptional transactivator of the HTLV-I LTR.^{57,153} It can also transactivate or inhibit cellular promoters by affecting the activity of the NF- κ B pathway, various transcriptional co-activators, and interleukin-2 (IL-2) signaling,^{72,283,333,430} and it induces defects in DNA replication and repair by nontranscriptional mechanisms.^{288,300} Tax has many properties

of an oncogene; for instance, it can transform rodent fibroblasts in culture, and mice harboring a *tax* transgene develop tumors of mesenchymal origin.³³³ Tax can also up-regulate telomerase expression, inactivate p53, and immortalize human T cells in the presence of IL-2.

WDSV and Dermal Sarcomas. Walleye dermal sarcomavirus (WDSV) is an epsilonretrovirus that induces dermal sarcomas in walleye pike.³⁸³ Related viruses (WEHV-1 and -2) induce epidermal hyperplasia in these fish, and similar viruses induce tumors in other fish. Tumors arise only during the winter; during spring spawning the tumors are shed, where the released virus presumably infects new hatchlings. WDSV and other epsilonretroviruses carry three additional reading frames besides the standard retroviral genes—*orf A*, *orf B*, and *orf C*. During the winter, the tumors do not express infectious virus, and the only transcripts present are for *orf A* and *orf B*, so the proteins encoded by these genes are likely involved in tumorigenesis.³⁸³ *Orf A* encodes a viral cyclin, rvCyclin, which binds cellular cdk8 and cdk3 and affects viral transcription and transformation. rvCyclin in complex with cdk8 negatively regulates transcription from the WDSV LTR and may be involved in inhibiting viral expression in the winter. rvCyclin can also affect expression of cellular genes, and it may positively affect cell transformation and tumorigenesis. Mice transgenic for rvCyclin develop squamous epithelial hyperplasia and dysplasia,²⁷⁴ but tumors do not form in transgenic rvCyclin fish.³⁵¹ *Orf B* may also contribute to tumorigenesis. This gene appears to have an antiapoptotic function, and *orf B* can transform cells in culture.³⁸³

JSRV and Env as an Oncogene. Jaagsiekte sheep retrovirus (JSRV) and the related enzootic nasal tumor virus (ENTV-1 and -2) are betaretroviruses. JSRV causes a transmissible lung cancer (ovine pulmonary adenocarcinoma) in sheep, and ENTV-1 and -2 cause adenocarcinoma of nasal epithelial cells in goats.²¹⁶ Interestingly, the native envelope protein of these viruses not only mediates viral entry but also functions as an oncogene. Expression of Env protein can transform various fibroblast and epithelial cells *in vitro*²⁹⁶ and induce tumors in mice or sheep.^{59,78,102,500}

As is the case for all retroviruses, there are two Env proteins, which are derived by cleavage from a polyprotein precursor—the SU (surface) protein on the exterior of virions and the TM (transmembrane) protein that spans the lipid bilayer of the viral envelope. In JSRV-transformed cells, the SU protein is presumably extracellular and the TM spans the plasma membrane. The intracellular cytoplasmic tail (CT) of TM is necessary for transformation, and a specific required tyrosine residue in CT might serve as a docking site for PI3K.³⁴³ Signal transduction pathways important for JSRV transformation include PI3K/Akt/mammalian target of rapamycin (mTOR) and Ras/Raf-MEK/MAPK.²⁹⁵ In addition to TM, the SU region of JSRV Env is also important for transformation.

Studies in a human lung epithelial line (BEAS-2B) suggested another mechanism for JSRV transformation. In these cells, JSRV Env binds hyaluronidase 2 (Hyal2), which itself binds and inactivates the Ron RTK (also known as STK).¹⁰⁶ Expression of JSRV Env leads to binding and degradation of Hyal-2, releasing Ron from inhibition. Signaling downstream from Ron involves the PI3K/Akt/mTOR and Ras/Raf-

MEK/MAPK pathways. However, JSRV Env is able to transform cells such as mouse fibroblasts, whose Hyal-2 does not bind Env and where Ron is not expressed.²⁸⁹ Thus, while binding and inactivation of Hyal-2 may participate in transformation of lung epithelial cells, this interaction is not required for transformation of other cell types.

As described earlier, MMTV induces mammary tumors by insertional activation of proto-oncogenes. However, MMTV envelope may also have oncogenic properties. MMTV-infected cell lines are not transformed when grown in monolayer culture. However, MMTV-infected MCF10 mammary epithelial cells show enhanced and disorganized growth when cultured in three dimensions, whereas normal MCF10 cells form well-organized spheres consisting of a single layer of polarized epithelial cells.²⁴⁸ This transforming activity requires an immunoreceptor tyrosine-based activation motif (ITAM) in the MMTV Env TM protein, which leads to signaling through pathways used for ITAM signaling in lymphocytes.²⁴⁸

Finally, as mentioned earlier, the oncogene of the acute transforming Friend SFFV virus encodes an internally deleted form of an endogenous MuLV Env protein recombined into F-MuLV, designated gp55.⁸⁵ Gp55 protein binds two growth factor receptors on the surface of erythroid cells: the erythropoietin receptor (EpoR)²⁸⁵ and the short form of STK (sfSTK)/Ron.³³⁹ Binding leads to constitutive downstream signaling from these receptors through signaling molecules such as Stat 3, Ras/Raf-MEK/MAPK, and PI3K/Akt.⁸⁵ Signaling through sfSTK appears to be more important for oncogenic transformation in some cell types, although in others EpoR signaling is sufficient.

MECHANISMS OF DNA VIRUS ONCOGENE ACTION

Overview

As shown in Table 7.1, several families of DNA-containing viruses induce transformation in cell culture or tumors in animals or humans. The DNA tumor viruses with the smallest genomes and clearly defined oncogenes are the polyomaviruses, including murine polyomavirus and SV40 (a polyomavirus of African green monkeys). Polyomaviruses have circular double-stranded DNA genomes of ca. 5,200 base pairs (bp) that encode two or three oncoproteins—the tumor (T) antigens (large T [LT], small T [sT], and in the case of murine polyomavirus, middle T [mT]). Papillomaviruses have slightly larger circular double-stranded genomes (ca. 8,000 kb) and cause warts in various species. Major oncogenic papillomaviruses include bovine papillomavirus (BPV) and oncogenic strains of HPV. Papillomaviruses encode three oncoproteins: E6, E7, and E5. Adenoviruses are common respiratory viruses with intermediate-sized, linear double-stranded DNA genomes (ca. 30 kb). Certain strains of human adenoviruses can induce tumors in rodents and transform rodent cells in culture. The major oncoproteins of adenovirus are encoded by the E1 region. In addition, adenoviruses express some less well-studied oncogenes, including adenovirus type 9 E4-orf1, which is a major determinant of estrogen-dependent mammary tumor formation in female rats.²³⁵ Herpesviruses are enveloped viruses with large double-stranded DNA genomes (100–150 kb). Several viruses

of the gammaherpesvirus genus induce tumors in their host species including humans. Oncogenic human herpesviruses include Epstein-Barr virus (EBV—primarily lymphomas and nasopharyngeal carcinomas) and KSHV (primarily Kaposi's sarcoma). Herpesviruses encode multiple oncoproteins. Another virus with a small DNA genome, hepatitis B virus, can cause tumors, but its mode of action remains poorly defined.

The mechanisms of action of many DNA tumor virus oncogene products are known in considerable detail, and several common features of DNA virus transformation have emerged. DNA virus oncoproteins are required for normal virus replication, typically acting during the early phase of infection prior to the onset of viral DNA replication or active in replication itself. Most DNA viruses encode more than one oncoprotein, which often cooperate to transform cells, in some cases because one protein negates the deleterious effects of the other one. Most commonly, these oncoproteins function by binding to cellular proteins and modulating their activities (Table 7.5). Often, a single viral oncoprotein can bind to numerous cellular targets. As is the case for transduced retroviral oncogenes, some DNA tumor virus oncoproteins stimulate cellular mitogenic

TABLE 7.5 DNA Virus Oncoproteins and Their Major Targets

Adenovirus E1A	Rb family members, p300/CBP, CtBP
Adenovirus E1B 19K	Bak, Bax
Adenovirus E1B 55K	p53
Adenovirus E4orf6	p53
Bovine papillomavirus E5	PDGF- β receptor
Epstein-Barr virus EBNA2	RBP-J κ /CBF1, glycogen synthetase kinase
Epstein-Barr virus LMP1	Tumor necrosis factor signaling components, PI3K
Epstein-Barr virus LMP2	Src family members
Hepatitis B virus X protein	p53
Herpesvirus saimiri STP	Tumor necrosis factor signaling components
Herpesvirus saimiri Tip	Src family members
Human papillomavirus E5	EGF receptor
Human papillomavirus E6	p53, PDZ proteins, E6-AP, DNA repair and apoptosis machinery
Human papillomavirus E7	Rb family members, p21, p27, p600
KSHV K-bZIP	p53
KSHV ORF 50	p53
KSHV vCyclin	Cyclin-dependent kinase 6
Polyomavirus large T antigen	p53 (not murine polyomavirus), Rb family members
Polyomavirus middle T antigen	Src family members, PI3K, PP2A, shc
Polyomavirus small T antigen	PP2A

EBNA, Epstein-Barr virus nuclear antigen; EGF, epidermal growth factor; KSHV, Kaposi sarcoma herpesvirus; LMP, latent membrane protein; PDGF, platelet-derived growth factor; PI3K, phosphatidylinositol 3-kinase; PP2A, protein phosphatase 2A.

FIGURE 7.9. Mitogenic signal transduction pathways and DNA virus oncogenes. In this diagram of mitogenic signal transduction, DNA tumor virus oncoproteins that mimic or modulate cellular signaling components are listed in red.

signal transduction pathways (Fig. 7.9), and these examples are described first. In a mechanism of action that is shared among several DNA viruses, other oncoproteins inactivate the Rb and p53 cellular tumor suppressor pathways (Fig. 7.9). It is striking that diverse DNA tumor viruses modulate a limited number of common cellular targets, implying that there are relatively few crucial nodes that regulate cell proliferation (Table 7.6).

DNA Virus Oncoproteins That Stimulate Mitogenic Signaling Pathways

Polyomavirus Middle T Antigen. mT is responsible for the major transforming activity of murine polyomavirus in established lines of rodent cells and can induce a variety of cancers in animals.⁴⁶⁸ mT is also important for productive polyomavirus infection by regulating viral DNA replication, transcription, and virion assembly.¹⁶⁰

mT is a 55-kD, largely cytoplasmic protein that is anchored in the plasma membrane by a C-terminal transmembrane segment (Fig. 7.10). Membrane association is required for mT activity, but the native mT transmembrane domain can be replaced by certain other membrane-targeting sequences.¹⁴⁴ The first clue to the mechanism of mT function came from biochemical studies showing that mT associates with protein kinase activity.¹³⁴ Further analysis revealed that mT is not an enzyme, but rather associates with a cellular nonreceptor tyrosine kinase. This cellular enzyme turned out to be none

TABLE 7.6 Common Targets of DNA Virus Oncogenes

<i>p53</i>	SV40 large T antigen High-risk HPV E6 Adenovirus E1B 55K and E4orf6 KSHV K-bZIP, LANA, and ORF 50 Hepatitis B virus X protein

<i>Src</i> family members	Middle T antigen EBV LMP2A HVS STP and Tip
<i>PI3K</i>	Polyomavirus middle T antigen, EBV LMP1
<i>PP2A</i>	Polyomavirus small T antigen and middle T antigen

EBV, Epstein-Barr virus; HPV, human papillomavirus; HVS, *Herpesvirus saimiri*; KSHV, Kaposi sarcoma herpesvirus; LANA, latency-associated nuclear antigen; LMP1, latent membrane protein 1; PI3K, phosphatidylinositol 3-kinase; PP2A, protein phosphatase 2A; SV40, simian virus 40.

FIGURE 7.10. DNA virus oncoproteins and receptor tyrosine kinases. **A:** An unstimulated receptor tyrosine kinase (RTK) exists as unphosphorylated monomer with an extracellular ligand binding domain, a membrane-spanning segment, and an intracellular catalytic domain. Horizontal lines represent the plasma membrane. **B:** Treatment with ligand induces receptor dimerization and tyrosine phosphorylation, which recruits various signaling proteins to the receptor. To simplify the drawing, only a single molecule of two substrates is shown. **C:** A dimer of the bovine papillomavirus E5 oncoprotein interacts the transmembrane domain of two molecules of the platelet-derived growth factor- β (PDGF- β) receptor, resulting in receptor dimerization, autophosphorylation, and recruitment of signaling proteins. **D:** Murine polyomavirus middle T antigen (mT) is anchored into the plasma membrane by a carboxyl-terminal transmembrane domain. Protein phosphatase 2A (PP2A) binds to the cytoplasmic domain of mT and recruits pp60^{c-src} (src), which catalyzes mT tyrosine phosphorylation and generates binding sites for signaling proteins.

other than pp60^{c-src}, the product of the *c-src* proto-oncogene!⁹⁶ mT also associates with some other members of the *src* kinase family.¹⁶⁰ Biochemical studies showed that mT activated the tyrosine kinase activity of pp60^{c-src} by preventing an inhibitory phosphorylation event at Y^{527,37,94}. These experiments drew the first connection between RNA and DNA tumor viruses and suggested that DNA viruses transformed cells, at least in this case, by causing biochemical activation of a cellular proto-oncogene product. This, of course, is what happens during oncogene transduction by the acute transforming retroviruses, but in the case of mT, activation was induced by binding to a viral protein and not by structural alterations in the proto-oncogene product itself. Nevertheless, these results provided a satisfyingly unified view of tumor virus action.

The importance of *c-src* for mT transformation was illustrated by experiments showing that down-regulation of *c-src* expression by RNA interference attenuated mT-mediated transformation.³ Similarly, knockout of *src* family members can inhibit tumor formation in mice expressing mT, but the interpretation of these experiments is complicated by redundancy between different members of the *src* family.^{160,464}

mT also binds to protein phosphatase 2A (PP2A), an important regulatory serine/threonine kinase.^{342,480} The major role of PP2A in mT function appears to be as a scaffolding factor that recruits *src* family members to the mT/PP2A complex. Consequently, mT mutants unable to bind PP2A are defective for pp60^{c-src} binding and transformation. Once bound to wild-type mT, activated pp60^{c-src} phosphorylates mT on several cytoplasmic tyrosine residues, thereby generating specific binding sites for cellular signaling proteins including

PI3K, phospholipase C γ , and shc, many of which are then tyrosine phosphorylated and activated by the *src* family kinase.^{95,462} Although the results are complex and influenced by the cell type studied, mutating these phosphorylation sites on mT often caused transformation and tumor-forming defects, suggesting that these binding partners are important for transformation.¹⁶⁰ For example, mutation of an asparagine-proline-threonine-tyrosine (NPTY) sequence in mT prevented transformation, but insertion of an ectopic NPTY motif elsewhere in mT restored the activity to the original transformation-defective mutant, suggesting that this motif functions as a modular protein-protein interaction motif.¹²⁶ Biochemical studies demonstrated that phosphorylation of the tyrosine in the NPTY motif generates a binding site for the adaptor protein shc.^{56,121} Once bound to mT, shc is tyrosine phosphorylated by pp60^{c-src}, allowing it to bind the SH2 domain of Grb2. Grb2 then recruits Sos to the mT signaling complex, and ras-MAPK signaling is activated.

Another major phosphorylation-dependent binding partner of mT is the p85 regulatory subunit of PI3K.^{246,493} Indeed, it was through studies of mT that PI3K was identified as a lipid kinase that phosphorylated phosphatidylinositol bisphosphate (PIP2) to generate the second messenger, PIP3. In mouse models of mT-mediated tumorigenesis, genetic knockout of the p110 α catalytic subunit of PI3K prevented tumor formation, highlighting the importance of PI3K signaling in mT transformation.⁴⁷¹ The main role of PIP3 is to activate proteins that contain pleckstrin homology (PH) domains by recruiting them to the plasma membrane. Targets of this mechanism include the kinases PDK1 and Akt,

which in turn phosphorylate their own substrates and regulate numerous important cellular processes, including apoptosis and cell growth.¹⁰¹

On the basis of these experiments, the following view of mT action has emerged. Membrane-anchored mT binds to PP2A, which allows it to bind and activate pp60^{c-src}, which in turn catalyzes tyrosine phosphorylation of the cytoplasmic domain of mT. This results in the recruitment and activation of a constellation of signaling molecules, which activate ras-MAPK signaling and block apoptosis. mT, then, can be viewed as a mimic of a constitutively active growth factor receptor, which assembles a phosphotyrosine-dependent signaling complex containing many of the same proteins at the cell membrane (Fig. 7.10).

Papillomavirus E5 Proteins. The BPV E5 gene can cause morphologic and tumorigenic transformation of cultured fibroblasts, reflecting the ability of BPV to cause fibroblastic tumors in animals. Only 44 amino acids long, E5 is the smallest autonomous oncoprotein. Even more strange is its extremely hydrophobic amino acid composition, resembling a membrane-anchoring domain of a transmembrane protein. Indeed, the E5 protein is essentially an isolated transmembrane domain that exists in the intracellular membranes of transformed cells as a disulfide-linked dimer.^{51,406,461} The role of E5 in the BPV life cycle is not known.

Analysis of transformed cells revealed that the E5 dimer simultaneously binds to the transmembrane domains of two molecules of the PDGF- β receptor, causing ligand-independent receptor dimerization and activation^{185,273,356,357} (Fig. 7.10). This results in tyrosine phosphorylation of the cytoplasmic domain of the receptor, recruitment and activation of cellular signaling proteins, and mitogenic signaling.¹²⁷ Thus, like *v-sis*, the oncogene of the simian sarcoma retrovirus, the E5 protein causes constitutive activation of the PDGF receptor. However, E5 does not resemble the natural ligand and uses entirely different biochemical interactions to drive receptor activation.

Numerous genetic, biochemical, and pharmacologic studies demonstrated the importance of PDGF- β receptor activation for transformation by the E5 protein.⁴⁶¹ Most notably, cells lacking PDGF- β receptor expression are not susceptible to E5-mediated transformation unless the receptor gene is introduced into the cells.^{127,187,337,461} Interestingly, the E5 protein activates an immature, intracellular form of the PDGF- β receptor, suggesting that signaling occurs from an intracellular location.^{51,357}

The ability of the BPV E5 protein to activate the PDGF- β receptor by transmembrane interactions suggested that it might be possible to reprogram the E5 protein to bind to other transmembrane protein targets by changing the sequence of its transmembrane domain.¹⁶¹ Indeed, by screening a library expressing several hundred thousand E5-like proteins with randomized transmembrane domains, Cammett et al⁵⁵ isolated an artificial 44-amino acid transmembrane protein that caused ligand-independent activation of the human erythropoietin receptor, a cytokine receptor unrelated to the PDGF- β receptor. Even though this small transmembrane activator bears no biochemical resemblance to erythropoietin, it is able to stimulate erythroid differentiation of primary human hematopoietic cells *in vitro*. It may be possible to extend this approach to

isolate artificial small transmembrane proteins that interact with many other transmembrane targets, providing a new approach to modulate cell activity.

The BPV E5 protein also associates with a 16-kD transmembrane subunit of the vacuolar H⁺-ATPase and appears to inhibit its ability to acidify intracellular organelles.^{186,399} It has not been firmly established if this E5 activity, which is shared with HPV E5 proteins,⁹⁰ is required for E5-mediated cell transformation.

The high-risk HPV E5 proteins display weak transforming activity in cultured cells and can induce epithelial hyperplasia and contribute to the development of cancer in transgenic mice. These proteins are also hydrophobic and short (about twice the size of their BPV counterpart). The HPV E5 proteins appear to increase the sensitivity of the EGF receptor to EGF, but the biochemical mechanism for this activity remains obscure.⁴⁴⁹ A functional interaction of the HPV16 E5 protein and the EGF receptor is responsible for the growth-promoting effects of the HPV16 E5 protein in transgenic mice.¹⁷⁵ The B-cell-associated protein, Bap31, has also been implicated in the proliferative effects of the HPV16 E5 protein.³⁷⁷ Although the role of E5 in HPV replication is poorly defined, it appears to be required for efficient, differentiation-dependent viral DNA replication and expression of the late viral genes.^{150,174}

Epstein-Barr Virus and Herpesvirus Saimiri. Although herpesviruses normally grow lytically, they can also establish a state of viral latency in which a limited subset of genes (the latency genes) are expressed. Latently infected cells do not produce progeny virus, but the viral genome is maintained in the cells as an extrachromosomal plasmid. In some circumstances, latently infected cells can reactivate lytic viral gene expression and produce infectious virus. The cells in which lytic infection takes place can be different from those where latency is established. For example, EBV replicates lytically in epithelial cells of the oropharynx, whereas latency is established in infected lymphocytes. Tumors induced by the gammaherpesvirus, such as EBV and KSHV, often express the latency genes.

EBV can convert primary B lymphocytes into long-term lymphoblastoid cell lines.^{213,362,451} It can also transform rodent fibroblasts growing in culture. Like the small DNA tumor viruses, EBV contains multiple oncogenes. The first EBV oncogene identified was latent membrane protein 1 (LMP1), which can transform established lines of rodent fibroblasts.⁴⁸¹ LMP1 is also essential for EBV-mediated transformation of human B lymphocytes.^{250,354} In transgenic mice, LMP1 can induce epithelial and B-lymphocytic hyperplasia, which can progress to lymphoma.²⁷¹

LMP1 is a dimeric, integral membrane protein with six membrane-spanning domains and a 200-amino acid cytoplasmic, carboxyl-terminal tail (Fig. 7.11). Sequences in the carboxyl-terminal tail of LMP1 that are required for lymphocyte transformation bind to several proteins that mediate signaling by the tumor necrosis factor- α (TNF- α) receptor.^{230,231,322} These proteins include several TNF receptor-associated factors (TRAFs), receptor interacting protein (RIP), and a TNF receptor-associated death domain (TRADD) protein.^{229,230,231,322} Constitutive association of these proteins with LMP1 activates a number of cellular transcription factors, including NF- κ B, c-Jun N-terminal kinase (JNK), and p38, resulting in up-regulation of several antiapoptotic proteins

FIGURE 7.11. Structure of latent membrane protein 1 (LMP1). The figure shows a schematic diagram of a dimer of Epstein-Barr virus LMP1 protein, a multi-pass, transmembrane protein (blue). The carboxyl-terminal segment of LMP1 binds to a number of cellular signal transduction proteins in the tumor necrosis factor- α pathway. Horizontal lines represent the plasma membrane.

including Bcl-2 and survivin.^{140,141,384} The LMP1 sequences bound by the TNF signaling proteins are homologous to binding sites in the pro-survival CD40 form of the TNF receptor active in B lymphocytes. Thus, LMP1 mimics a constitutively active CD40 TNF receptor to deliver a pro-survival signal.⁴⁶⁹ The cytoplasmic tail of LMP1 also binds the p85 subunit of PI3K, which may contribute to its pro-survival effects by activating akt.¹⁰⁷

EBV also expresses a structurally related protein, LMP2A, which contains 12 transmembrane segments. In epithelial cells, LMP2A can induce features of transformation, but most studies of LMP2A have been carried out in lymphocytes. LMP2A binds to the *lyn* tyrosine kinase, a member of the *src* family, resulting in inhibition of B-cell antigen receptor signaling.^{54,313,314} Because B-cell receptor signaling induces EBV to enter the lytic replication cycle, LMP2A can inhibit viral reactivation and allow the persistence of latently infected cells. LMP2A also mediates B-lymphocyte survival by activating akt signaling.^{363,456}

Studies of replication-competent EBV strains unable to transform lymphocytes revealed that the Epstein-Barr virus nuclear antigen 2 (*EBNA2*) gene is required for lymphocyte transformation.^{87,190,203} The EBNA2 protein is a nuclear phosphoprotein that transactivates the expression of several EBV genes, including LMP1, as well as numerous cellular genes involved in cell proliferation, including *c-Myc* and *CD23*.⁴⁸² EBNA2 acts by forming a complex with the cellular site-specific DNA binding protein, RBP-J κ /CBF1.^{197,286} Once bound to DNA, EBNA2 recruits additional transcription factors to promoters to mediate gene induction.²⁴⁰ The activated cellular receptor for Notch also stimulates transcription through RBP-J κ , so EBNA2 can be regarded as a mimic of a constitutively active Notch receptor. Consistent with this view, activated Notch can partially restore B-cell-transforming activity to EBV lacking EBNA2.¹⁸⁹

EBV expresses additional antiapoptotic proteins that can contribute to tumorigenesis. For example, the *BHRF1* gene product is homologous to the cellular antiapoptotic protein, Bcl-2, and binds and inhibits the pro-apoptotic activities of a number of cellular pro-apoptotic proteins including Bim, Bak, and Puma.²¹⁴

Herpesvirus saimiri (HVS) infects nonhuman primates and causes T-cell lymphomas in new world monkeys. The STP oncogene of HVS, like EBV LMP1, transforms lymphocytes by activating NF κ B via TNF receptor signaling molecules.¹⁰⁴ The STP protein of subgroup A HVS also associates with pp60^{src}. The HVS Tip oncoprotein interacts with *lck*, another *src* family kinase, and inhibits T-cell receptor signaling.²⁹

DNA Virus Oncoproteins That Inactivate Rb or p53

As described in this section, several DNA tumor viruses inactivate the Rb pathway. This induces a p53-dependent stress response that can result in growth arrest or apoptosis, either of which would limit virus production.^{137,445} There are multiple pathways that lead to p53 activation. In one such pathway, E2F1 released by Rb neutralization increases expression of p19^{ARF}.⁵¹⁵ p19 in turn stabilizes p53 by interfering with mdm2, a ubiquitin ligase that would otherwise destabilize p53.⁴⁴⁷ To inhibit the antiviral response elicited by Rb inactivation, viruses engage mechanisms to block p53 function. Thus, many DNA tumor viruses inactivate p53 as well as Rb to neutralize the pro-apoptotic signals initiated by Rb inactivation. The one known apparent exception to this shared strategy among the small DNA tumor viruses is murine polyomavirus. Polyomavirus LT binds Rb but does not bind p53. mT also lacks p53 binding. Therefore, this virus evidently has developed a strategy to overcome the deleterious effects of Rb neutralization without expressing a protein that directly inactivates p53. Viral oncogenes that target Rb and p53 are described in the following sections.

Adenovirus Oncogenes. Early studies revealed that adenovirus-transformed cells invariably retained only the *E1A* and *E1B* genes at the left end of the viral genome, suggesting that these were the major viral oncogenes.^{123,167} Indeed, transfection studies demonstrated that these genes had transforming activity and that full transformation required both *E1A* and *E1B*.²⁴² The 12S *E1A* gene product can stimulate cellular DNA synthesis and immortalize cells on its own, but it requires a cooperating oncogene such as *E1B* or activated *ras* to cause full transformation of primary rat embryo fibroblasts.³⁸⁸ As is the case for most DNA tumor virus oncogenes, *E1A* and *E1B* are required for normal productive infection.

Adenovirus *E1A*. Comparison of the amino acid sequences of *E1A* proteins from various strains of adenoviruses revealed that they shared a number of conserved motifs including conserved region 2 (CR2), which contains the sequence leucine-X-cysteine-X-glutamic acid, where X can be any amino acid (the LXCXE motif) (e-Fig. 7.3). Mutational analysis demonstrated that CR2 was required for transformation. Strikingly, SV40 LT and HPV E7 proteins also contain required LXCXE motifs,^{242,495} even though they are otherwise unrelated to *E1A* or each other (e-Fig. 7.3). Substitution of the LT CR2 region into a transformation-defective *E1A* mutant lacking its own CR2 restored transforming activity, suggesting that CR2 might constitute a discrete binding site for a cellular protein required for transformation.³¹⁸ Based on the precedent of the association of mT and *src*, it seemed plausible that the CR2 motif of *E1A* bound to the product of a cellular oncogene and activated it, resulting in transformation.

To identify cellular proteins that bind to *E1A* and possibly mediate transformation, *E1A* antibodies were used to immunoprecipitate *E1A* and associated cellular proteins from infected cell extracts.^{206,507} A 105-kD *E1A*-associated protein was soon identified as the product of the *RB1* gene.⁴⁹⁴ *RB1* encodes the retinoblastoma tumor suppressor protein, p105^{Rb}, and had been previously implicated in retinoblastoma, a hereditary cancer of the eye. Notably, in retinoblastoma, *RB1* acts not as an oncogene, but rather as a tumor suppressor gene, whose loss predisposes individuals to tumor development. Mutations in *E1A* CR2 that blocked p105^{Rb} binding also inhibited transformation.³⁷⁶ Biochemical and gene transfer experiments showed that the association of *E1A* and p105^{Rb} freed E2F from repressive Rb/E2F complexes, resulting in increased transcription of E2F-regulated genes^{16,71,376} (Fig. 7.12). These seminal and at the time surprising findings showed that viral oncogenes can transform cells not only by activating the products of cellular proto-oncogenes but also by inactivating cellular proteins that inhibit cell proliferation. The ability of *E1A* to inactivate p105^{Rb} was foreshadowed by the observation that injection of adenovirus type 12 into the eyes of newborn rats caused retinoblastoma.²⁶⁰

Two additional members of the retinoblastoma tumor suppressor family, p107 and p130, also bind *E1A*. Because all three Rb family members evidently share a structural pocket that binds to the LXCXE motif on various viral oncoproteins, these Rb family members are sometimes referred to as the pocket proteins.

In addition to CR2, conserved sequences in the amino-terminus of *E1A* (CR1) are also required for induction of DNA synthesis and transformation (but not for Rb binding),

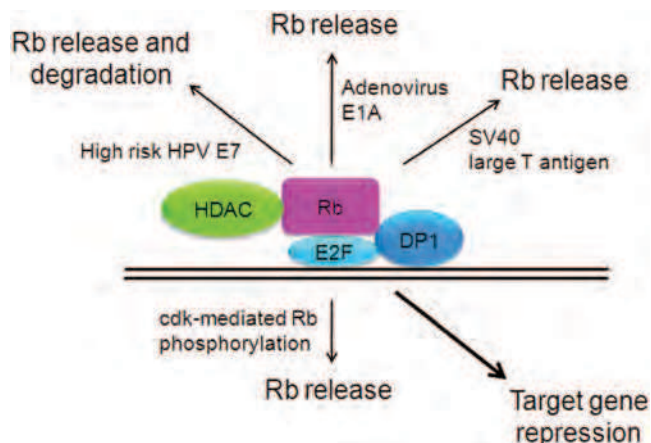

FIGURE 7.12. Interaction between retinoblastoma proteins and DNA tumor virus oncoproteins. Retinoblastoma (Rb) family members in complex with an E2F/DP1 heterodimer recruit histone deacetylases (HDACs) to promoters, resulting in their repression. Horizontal lines represent double-stranded DNA. Repressive complexes are disrupted in uninfected cells by cdk-mediated phosphorylation of Rb, allowing E2F to stimulate transcription. The effects of oncoproteins from three unrelated DNA tumor viruses are shown above the DNA.

implying that there are additional cellular targets of *E1A* involved in transformation.⁴⁹⁵ These sequences bind to p300 and CBP, closely related histone acetyl transferases that are co-activators for the CREB transcription factor.⁶ These proteins presumably contribute to transformation by directly regulating the activity of cellular genes. SV40 LT and high-risk HPV E7 also bind p300/CBP, as well as Rb. The extreme C-terminus of *E1A* binds a cellular protein, CtBP, a transcriptional co-repressor.³⁹⁷ Deletion of this binding site affects the ability of *E1A* to cooperate with other oncogenes.⁷⁷

Adenovirus *E1B*. Co-expression of adenovirus *E1A* and *E1B* genes can cause cell transformation.²⁴² However, in the absence of *E1B*, acute expression of *E1A* causes a burst of cellular DNA synthesis followed by a dramatic cellular phenotype involving degradation of viral and cellular DNA and cell death.^{8,359,370,491} This phenotype is now recognized as apoptosis and is a response in large part to the unscheduled DNA synthesis elicited by the inactivation of Rb by *E1A*. Thus, a major function of *E1B* is to counter *E1A*-induced apoptosis.^{110,370} How does *E1B* accomplish this? There are two unrelated *E1B* protein products encoded by alternatively spliced mRNAs, each of which can independently cooperate with *E1A*. The 55-kD *E1B* product of adenovirus binds to p53, which is required for *E1A*-induced apoptosis, and neutralizes its activity.^{110,390,391,396} The importance of p53 inactivation for transformation was shown by the ability of dominant-negative p53 (see next section) to cooperate with *E1A* in inducing transformation of primary cells.³⁸⁸ The adenovirus E4orf6 protein can also cooperate with *E1A* to transform cells by inhibiting p53 function, and in cooperation with *E1B*-55K causes the degradation of p53.⁴³⁸ The complete absence of amino acid sequence homology between *E1B*-55K, E4orf6, SV40 LT, and HPV E6, proteins that all inactivate p53, is a striking example of convergent evolution and highlights the need of diverse DNA tumor viruses to interfere with p53 activity.

The smaller E1B gene product, E1B-19K, also inhibits E1A-mediated apoptosis.^{370,492} E1B-19K is homologous to the cellular *Bcl-2* gene family that regulates apoptosis.⁴²³ E1B-19K inhibits apoptosis by sequestering the pro-apoptotic family members Bak and Bax and preventing the formation of pores in the mitochondrial outer membrane and the release of pro-apoptotic proteins such as cytochrome c.⁴⁹²

SV40 Large T Antigen. LT is a multifunctional protein required for SV40 DNA replication, late gene expression, and other aspects of the viral lytic life cycle.² It is also the major oncoprotein of SV40, and expression of LT in transgenic mice can give rise to a number of tumors including choroid plexus tumors, retinoblastoma, pancreatic carcinoma, and intestinal hyperplasia. At least three segments of LT are required for transforming activity: a J domain and a conserved LXCXE motif in the amino-terminal half of the protein, and a distinct segment in the carboxyl-terminal half.² The relative importance of these segments depends on the transformation assay employed, but in some assays the amino-terminal half of LT was sufficient for transformation. In addition, a second early protein of SV40, small t antigen, which shares amino acid sequences with the amino-terminus of LT, can contribute to transformation under some conditions, apparently by inhibiting PP2A.^{30,392,505,510}

Soon after it was discovered that adenovirus E1A bound p105^{Rb}, LT was also found to bind the Rb family.¹¹² Furthermore, assay of a series of point mutations in the LT LXCXE motif demonstrated that Rb binding was required for transformation. The molecular chaperone function of the J domain of LT is also required for Rb inactivation by recruiting an Hsp70 activity to remodel the Rb/E2F complexes and release free E2F to activate cellular genes required for cell proliferation.^{111,424,450} Thus, two otherwise unrelated transforming proteins, adenovirus E1A and SV40 LT, shared a common property, namely, the ability to bind to and neutralize Rb proteins (Fig. 7.12).

Rb family members are not the only cellular proteins bound by LT. In fact, the well-known tumor suppressor protein, p53, was first discovered as an LT binding protein. The analysis of p53 was initially confusing and is a tale worth telling. Antibodies that recognized LT also co-immunoprecipitated a cellular protein called p53.^{276,287} In general, p53 levels were high in LT-transformed cells. p53 binding mapped to the C-terminal segment of LT required for transformation, and LT mutants unable to bind p53 were transformation defective.^{2,516} In addition, molecular clones of the *p53* gene from immortalized mouse cell lines displayed transforming activity in cooperation with validated oncogenes such as *v-ras*, and the *p53* gene was amplified in human sarcomas.^{142,236,341,345} These results strongly suggested that p53 was an oncogene product. This led to the conclusion that LT bound and activated the product of a cellular oncogene (namely, p53), resulting in transformation.

Results soon accumulated that challenged this apparently straightforward interpretation. First, some proviral integration sites in retrovirus-induced leukemias actually disrupted the *p53* gene, rather than activated it.²⁴¹ Second, inactivating p53 mutations were frequently found in naturally arising sporadic human tumors, as well as in some familial cancers, where mutant p53 displayed a pattern of inheritance consistent with tumor suppressor function.^{284,298} Mice engineered to lack p53 displayed a higher incidence of spontaneous tumor forma-

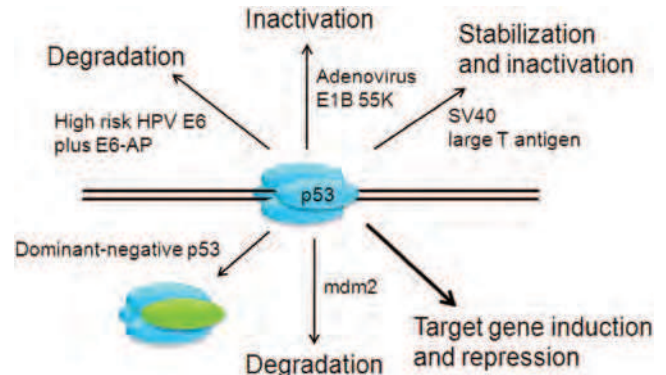

FIGURE 7.13. Interaction between p53 and DNA tumor virus oncoproteins. A tetramer of p53 bound to double-stranded DNA is shown in blue at the middle. The ability of p53 to regulate gene expression can be inactivated in uninfected cells by mdm2-mediated p53 degradation or by expression of a dominant negative mutant of p53, which forms an inactive tetramer. The effects of three oncoproteins from unrelated DNA tumor viruses are shown above the DNA.

tion.¹²⁴ In addition, the interaction with LT did not stimulate the transcriptional activity of p53 but rather blocked it.³¹² Finally, independent molecular clones of the *p53* gene from primary, nonimmortalized cells did not display transforming activity, but inhibited cell growth.^{11,156} The role of p53 was finally resolved with the discovery that the original cloned *p53* genes that displayed transforming activity were actually mutants. The wild-type *p53* gene acts not as an oncogene but as a tumor suppressor gene.²⁸⁴ Thus, as was the case with E1A or LT with Rb, LT transforms cells in part by inactivating the tumor suppressor activity of p53 (Fig. 7.13).

Certain p53 mutants with transforming activity are said to be dominant negative, because they hetero-oligomerize with the wild-type version of p53 and neutralize its activity.²⁸⁴ Expression of such a mutant effectively titrates active p53 from the cell and is functionally equivalent to the loss of both p53 alleles, as is the case for a classic inherited tumor suppressor gene. Such p53 mutations are some of the most common genetic alterations in human cancer.

Human Papillomavirus Nuclear Oncogenes. E6 and E7 encode short nuclear proteins (~100 amino acids), which are required for productive infection.¹⁵⁸ The high-risk HPV *E6* and *E7* genes cooperate to immortalize primary human keratinocytes, the progenitor cells of cervical and other squamous cell cancers; block the terminal differentiation of these cells; and disrupt genomic integrity.^{22,209,325,405,490} The ability of HPV to immortalize cultured cells correlates with their oncogenic potential in patients—proteins from the high-risk HPV types have increased activity in comparison to the low-risk proteins.^{17,353,446,499} The *E6/E7* genes from high-risk HPV can also induce a variety of tumors in transgenic mice, including cervical cancer in mice chronically treated with estrogen.⁷ In addition, the high-risk but not low-risk E7 protein can stimulate DNA synthesis in resting cells and transform rodent cells either on its own or in cooperation with the *v-ras* oncogene.^{244,479} As is the case for LT and E1A/E1B, a major activity of E6 and E7 is to neutralize p53 and Rb.

Human Papillomavirus E7. The E7 protein is not an enzyme, but rather modulates the activity of regulatory proteins encoded by the host cell. Like LT and E1A, the HPV E7 protein contains an LXCXE motif that binds to the Rb family pocket proteins.^{133,326} This results in the displacement of Rb proteins from E2F family members and in degradation of Rb^{45,71} (Fig. 7.12). Although the LXCXE motif is sufficient for Rb binding, sequences outside of this motif are required for degradation and complete inactivation of Rb. The mechanism of Rb degradation is not understood completely but appears to involve the assembly of a cullin 2 ubiquitin ligase complex with Rb, followed by proteosomal degradation.²²⁰

Repression of E7 expression in cervical cancer cells results in the loss of hyperphosphorylated Rb and the induction of the hypophosphorylated, growth inhibitory form of Rb that binds E2F.¹⁸⁸ This in turn results in repression of E2F-responsive genes and growth arrest, demonstrating that continuous association with E7 is required for sustained Rb inhibition.

Several lines of evidence suggest that the transforming activities of E7 depend on its ability to neutralize the Rb family. Both high-risk and low-risk E7 proteins contain the LXCXE motif, but the affinity of HPV E7 proteins for p105^{Rb} correlates with the oncogenic potential of the virus: high-risk E7 binds p105^{Rb} tightly; low-risk E7 binds it poorly.^{166,326} These differences map to a single amino acid immediately adjacent to the LXCXE motif, which determines the ability of E7 to transform rat kidney cells in cooperation with the *ras* oncogene.²¹² In addition, E7 can be replaced in an E6-dependent keratinocyte immortalization assay by down-regulation of the cdk inhibitor p16^{INK4a}, a manipulation that also inactivates p105^{Rb} by allowing its phosphorylation and release from E2F.²⁵⁵ These results suggest that inactivation of the Rb family by E7 is important for cell transformation, keratinocyte immortalization, and cervical carcinogenesis. On the other hand, transformation assays carried out with E7 mutants defective for various activities have not yielded consistent results, although some experiments suggest that Rb binding is essential for transformation.^{237,309} In transgenic mice, the ability of E7 to neutralize Rb function is tightly linked to its ability to support DNA synthesis in differentiating epithelial cells, but not for cervical carcinogenesis.^{13,14}

The E7 proteins can also affect cellular checkpoint control. High-risk E7 interacts with two cdk inhibitors, p21^{CIP1} and p27^{KIP1}, and abrogates their growth inhibitory effects.^{116,165,432,513} These E7 activities may also contribute to the ability of E7 to induce resistance to growth inhibitory cytokines such as transforming growth factor- β , tumor necrosis factor, and interferon.^{18,19,348,358} The signals mobilized by the E7 protein maintain the proliferative status of suprabasal keratinocytes, which otherwise undergo terminal differentiation and become unable to support DNA synthesis. These signals thereby allow viral DNA replication and the production of progeny virus in the stratified epithelium.^{14,76}

The E7 proteins bind to a large number of additional cell proteins.³⁰⁹ Some of these binding partners, such as various cyclins and E2F family members, are likely to reinforce the activities mentioned previously. p600, an Rb-associated protein, associates with both high-risk and low-risk E7 and appears to allow the survival of cells in the absence of anchorage and may thus contribute to malignancy.^{115,221} Other E7 binding partners include histone-modifying enzymes and members of the polycomb group transcriptional repressor complexes,

suggesting that E7 may affect epigenetic status.³⁰⁹ However, the biological relevance of most of the interactions of the E7 protein with cellular proteins is not known.

Cervical cancer cells are often aneuploid and contain other chromosomal abnormalities, which presumably play a role in malignant progression. The high-risk E7 protein induces genomic instability in part by interfering with the synthesis or function of centrosomes, the subcellular structures that form the poles of the mitotic spindle to ensure proper chromosome segregation during mitosis.¹²⁸ Primary human epithelial cells expressing E7 often contain abnormal or supernumerary centrosomes due to the uncoupling of centriole synthesis from cell cycle progression. The molecular mechanism by which E7 interferes with centrosome synthesis is not known in detail, but it is at least in part independent of Rb targeting and may involve interactions with cellular proteins involved in centrosome activity or mitosis.^{129,334}

Human Papillomavirus E6. Like the E7 protein, the HPV E6 protein lacks enzymatic activity and functions by modulating the activity of cellular proteins.²¹⁸ The high-risk E6 protein is able to immortalize human mammary epithelial cells on its own,¹⁵ but most analyses of E6 have been conducted in keratinocytes and focus on its ability to cooperate with E7. A number of the signaling pathways stimulated by the E7 protein, including unscheduled DNA synthesis due to Rb inactivation, tend to drive cells into apoptosis.^{137,445} A major role of E6 is to limit this deleterious cellular response to E7 expression.

The E6 protein from the high-risk HPV types binds to a number of cellular proteins and induces their ubiquitin-mediated degradation.²¹⁸ The proximal target of the E6 protein is the E3 ubiquitin ligase, E6-associated protein (E6-AP).^{222,402} The direct binding of E6 to a leucine-X-X-leucine-leucine motif on E6-AP reprograms it to ubiquitylate a number of cell proteins, which leads to their proteasome-mediated degradation.^{400,402} The most prominent target of E6/E6-AP is p53, which is normally a substrate of a different ubiquitin ligase, mdm2, not E6-AP.^{74,208,489,502} (Fig. 7.13). Although p53 is wild type in most cervical carcinoma cell lines, it has a short half-life and its levels are low in these cells because of E6-mediated degradation.^{312,401} As a consequence, p53-dependent checkpoint controls, for example, in response to Rb inactivation or DNA damage, are blunted although not necessarily eliminated in cells expressing high-risk E6 proteins.^{53,490} The low-risk E6 proteins do not induce p53 degradation. Mutant p53 can replace HPV16 E6 in inducing keratinocyte immortalization, implying that E6-mediated p53 inactivation is important for this activity.⁴¹⁴ In addition to E6-AP-mediated degradation, there appear to be several other mechanisms utilized by E6 to attenuate p53 activity.²¹⁸ Repression of E6 expression in cervical cancer cells results in the elevation of p53 levels and restoration of p53 signaling, indicating that continuous association with E6 is required for sustained p53 inhibition.¹¹³

The E6 proteins also exert p53-independent antiapoptotic effects.²⁷² High-risk E6 blocks several steps in the extrinsic apoptosis signaling cascade by interacting with a death receptor (tumor necrosis factor receptor-1), the FAS-associated via death domain (FADD) adaptor protein, and caspase-8.¹⁵⁵ E6 also inhibits the intrinsic apoptotic pathway by binding to the pro-apoptotic molecule Bak and inducing its proteasome-dependent degradation, thereby blocking release of apoptotic mediators from

mitochondria.⁴⁶⁵ In addition, HPV16 E6 and E7 can up-regulate two cellular inhibitors of apoptosis, c-IAP2 and survivin, which act farther downstream in the apoptosis signaling cascade.^{40,233,512} In concert, this barrage of antiapoptotic action prevents cell death and sets the stage for ongoing proliferation in response to E7 signals. Indeed, the ability of E6 from some HPVs to inhibit ultraviolet light-induced apoptosis has been proposed to be a prime contributor in HPV-associated skin cancer.²³²

In E6-expressing cells, E6-AP (and possibly other ubiquitin ligases) also ubiquitylates and causes the degradation of a series of PDZ domain-containing proteins^{171,303} (Fig. 7.13). These proteins are recruited to the E6/E6-AP ubiquitylation complex by binding to a serine/threonine-X-valine consensus PDZ domain binding motif at the extreme C-terminus of high-risk E6 proteins.^{256,280} These PDZ proteins include a number of proteins with presumed tumor suppressor activity, including Scribble, hDlg, and MAGI-1, which regulate signal transduction, cell-cell contact, and cell polarity. Loss of these proteins disrupts the formation of epithelial tight junctions and may contribute to the invasiveness of cervical cancer cells.^{269,486} E6 also promotes the degradation of several PDZ domain-containing protein tyrosine phosphatases, which regulate growth factor signaling pathways.⁴³⁶ The biological importance of PDZ binding was demonstrated by the finding that deletion of the PDZ binding motif from E6 affected viral genome replication and abrogated its ability to transform keratinocytes and stimulate epithelial hyperplasia in transgenic mice.^{278,335,486} Other viral oncoproteins, such as rhesus papillomavirus E7 (but not E6) and adenovirus E4-orf1, also bind PDZ proteins.⁴⁶⁶

Another consequence of E6 expression is transcriptional induction of the gene encoding hTERT, the catalytic subunit of telomerase, the ribonucleoprotein that maintains the ends of chromosomes.^{259,475} Introduction of hTERT can replace E6 in a keratinocyte immortalization assay,²⁵⁵ suggesting that hTERT induction is a crucial activity of E6. It has been proposed that E6-AP-mediated degradation of NFX1-91, a transcriptional repressor of the *hTERT* gene, is involved in hTERT induction by E6, although E6 probably exerts additional layers of control on telomerase.¹⁷⁷ Indeed, E6 also interacts with the telomerase complex and activates it posttranscriptionally.²⁹⁰ Other targets of E6-AP-mediated degradation include several GAPs, which regulate the activity of ras-like proteins, and proteins involved in DNA replication and repair.²¹⁸ E6 also inhibits O(6)-methylguanine-DNA methyltransferase, a crucial DNA repair enzyme,⁴³⁷ and the DNA repair scaffolding protein, XRCC1.²²⁸

In summary, it appears that the main biochemical activity of E6 is to redirect the E6-AP ubiquitin ligase to a number of cellular proteins with tumor suppressor or related activity, inducing their degradation. Knockout of the *E6-AP* gene in transgenic mice prevents the development of E6-mediated cervical cancer, demonstrating that E6-AP is required for this biological activity of HPV E6.⁴¹⁹

KSHV Oncogenes. Cells latently infected with KSHV express latency-associated nuclear antigen (LANA), a large, multifunctional nuclear protein required for the establishment and maintenance of the extrachromosomal viral genome.^{12,93} LANA can transform cultured fibroblasts in cooperation with activated *ras* and extend the life span of human endothelial

cells. In transgenic mice, LANA causes lymphocyte hyperplasia and, rarely, the development of lymphomas.^{147,368,485} Like the oncoproteins of many other DNA tumor viruses, LANA binds and neutralizes p53 and Rb.^{162,368,379} In addition, by binding to glycogen synthetase kinase 3 β , LANA modulates β -catenin and up-regulates expression of genes involved in cell proliferation such as cyclin D and c-myc.¹⁶³ The KSHV ORF50 and K-bZIP proteins also interfere with p53 activity.^{200,347}

The KSHV K1 protein contains two ITAM motifs and mimics signaling by the B-cell antigen receptor by activating the src family kinase *lyn*.³⁶⁵ The signals constitutively emanating from K1 inhibit apoptosis and can transform cells in a variety of settings.^{279,366} Another KSHV gene with transforming activity is *K12*, which encodes a series of active gene products.³²⁷ These include kaposin B, a mixture of short polypeptides that appear to function by activating the p38-MK2 pathway and stabilizing cellular mRNAs encoding pro-proliferative cytokines.³⁰⁸

In addition to the genes mentioned above, the KSHV genome also contains numerous genes that are clear homologs of cellular genes that stimulate proliferation or block apoptosis.³²⁸ These encode proteins that function as cytokines, a cyclin (v-Cyc), a constitutively active G-protein-coupled receptor (vGPCR), and a variety of other regulatory proteins. v-Cyc activates cdk6 that allow cell cycle progression.^{67,184} v-Cyc appears to be resistant to cdk inhibitors, and a v-Cyc/cdk6 complex can phosphorylate and inactivate p27^{KIP1}, itself a cdk inhibitor, thus reinforcing the pro-proliferative response caused by cdk-mediated phosphorylation of Rb.⁴⁵⁵ vIRF and vIL-6, homologous to interferon regulatory factors and interleukin-6, respectively, can also promote cell growth.^{69,169} vGPCR displays transforming activity in cultured fibroblasts and primary endothelial cells, and it can induce tumors that resemble KS in mice.⁹ Biochemical studies showed that vGPCR activates various mitogenic and pro-survival signaling pathways.^{58,316} KSHV also expresses at least three additional gene products that inhibit apoptosis: v-Bcl, which is homologous to Bcl-2 and acts by maintaining mitochondrial integrity; vIAP (viral inhibitor-of-apoptosis protein), which is homologous to a different cellular antiapoptotic protein, survivin; and vFLIP, which is thought to block apoptosis by inhibiting the Fas death receptor pathway or up-regulating NKkB.^{23,70,75,122,183,199,453,483} These activities contribute to lymphomagenesis in transgenic mice.⁸³ Several KSHV gene products also stimulate angiogenesis⁴³ in this highly vascularized tumor. For example, vGPCR signaling induces the expression of the angiogenic factor vascular endothelial growth factor (VEGF),⁵⁰⁶ and the KSHV chemokine viral macrophage inflammatory protein-1 (v-MIP-1) promotes angiogenesis by inducing VEGF expression and stimulating the chemotaxis of endothelial cells.⁴⁴⁴ Finally, it should be noted that herpesviruses express many gene products that down-regulate the innate and adaptive immune response. These activities are presumably of critical importance for tumor formation in otherwise immunocompetent animals.

Noncoding RNAs and Transformation. Many DNA tumor viruses express microRNAs and other noncoding RNAs (ncRNAs). EBER1 and EBER2, ncRNAs expressed by Epstein-Barr virus, can induce several features of transformation in cultured lymphocytes, including tumorigenicity in immunodeficient mice.^{263,387,504} The biochemical activities of the EBERs responsible for transformation are not known. KSHV encodes miR-K12-11 microRNA, which shows many

similarities to the growth-promoting cellular microRNA, miR-155.¹⁹¹ HVS encodes five small ncRNAs that form ribonucleoprotein complexes and induce the expression of numerous T-cell activation genes, at least in part by causing the degradation of specific cellular microRNAs.⁶³

VIRUSES AND HUMAN CANCER

Because viruses cause cancer in animals, it was natural to ask if they cause cancer in humans. The search for human tumor viruses began in earnest with the discovery of murine leukemia virus in the early 1950s¹⁹⁶ and took on special urgency in the 1960s with the startling discovery that some early stocks of the poliovirus vaccine were contaminated with live SV40, which has potent tumor-inducing activity in newborn hamsters.^{135,176,181} The SV40 contamination resulted from growing poliovirus in primary African green monkey kidney cells, some of which harbored SV40. Despite the suspected association between viruses and cancer, it took many years to assemble convincing evidence that viruses play an etiologic role in human cancer. Epidemiologic and laboratory studies designed to implicate viruses in human cancer were difficult because human tumor viruses do not act rapidly or efficiently. Rather, cancer arises only years or even decades after the initial infection, and most infected people do not get cancer, suggesting that virus infection represents only one step in carcinogenic progression and that additional cellular alterations must occur for cancer formation. In addition, many tumor virus infections (e.g., EBV, HPV, and HBV) are quite common, complicating attempts to forge epidemiologic links to specific cancers. Finally, virally induced tumors usually do not produce virus particles, obscuring the viral cause of some cancers.

Despite these challenges, six viruses are now generally recognized as playing causal roles in cancers that account for approximately 15% of all human cancer deaths worldwide^{310,317} (Table 7.7). These virus-induced cancers tend to be much more common in the developing world, where they can be the most common cause of cancer death. Virus-induced cancers also

occur relatively frequently in immunosuppressed individuals. Because viruses provide well-defined targets for prevention and therapy, virally associated cancers appear to represent a class of tumors that are particularly susceptible to rational prevention and treatment approaches.

Human Papillomaviruses

The HPVs cause papillomas or warts, benign tumors of epithelial cells in the skin and mucous membranes. Although warts are usually self-limited, genital warts (condyloma acuminata) and laryngeal papillomas can be serious medical conditions. The main medical importance of the HPVs derives from their association with human cancer.⁵¹⁸ High-risk strains of HPV such as HPV16 and HPV18, which were first discovered in cervical cancer samples,^{42,132} are responsible for virtually all cancers of the uterine cervix and a substantial fraction of other anogenital and oropharyngeal cancers in both men and women. Additional HPV types are associated with severe warts and skin cancer in immunosuppressed individuals.

As described earlier, the major oncogenes of the high-risk genital HPV are the *E6* and *E7* genes, which are continuously expressed in cancer cells.^{10,412} However, keratinocytes transformed *in vitro* by E6/E7 are not initially tumorigenic in experimental animals, implying that HPV-infected cells must accumulate additional mutations or other events to form cancers.^{131,224} This requirement for additional, presumably rare events may account for the observation that most people infected with high-risk HPV do not develop cancer. It is also likely to account for the long period of time that usually passes between infection and development of cancer. In most cervical cancers, the gene encoding the HPV E2 transcription factor is disrupted or its action is inhibited by mutation or epigenetic modification.⁸¹ This prevents E2-mediated repression of the promoter driving E6 and E7 transcription, and the resulting increased expression of the oncogenes presumably plays a role in carcinogenesis.

The finding that the E6 and E7 proteins from the high-risk HPV types are more effective at inhibiting the p53 and Rb tumor suppressor pathways than are the low-risk types, such as HPV6 and HPV11, implies that these interactions are important in human carcinogenesis.^{166,326} Similarly, the presence of wild-type *p53* and *Rb* genes in most cervical cancers implies that these pathways are neutralized by a nonmutational mechanism in these cells (i.e., by the expression of the viral oncoproteins).^{401,501} Continuous expression of the HPV *E6* and *E7* genes is required to maintain the Rb and p53 pathways in an inactive state in cervical carcinoma cells, and repression of E6/E7 rapidly activates these pathways and inhibits cell survival and proliferation.^{188,225,439,477} The third viral oncogene, the *E5* gene, is expressed in some but not all cervical cancers, and its role in human carcinogenesis is unclear.

Prophylactic vaccines formulated from virus-like particles (VLPs) composed of L1, the major HPV capsid protein, are very effective at raising neutralizing antibodies to the HPV types in the vaccine and preventing infection with these HPV types.^{267,403} These vaccines are likely to prevent many cases of HPV-associated cancers, but because of the long lag between the time of initial infection and cancer development, it will take many years to document this effect. In addition, a therapeutic vaccine composed of HPV16 E7 peptides has shown

TABLE 7.7 Human Tumor Viruses

Epstein-Barr virus	Burkitt lymphoma Nasopharyngeal carcinoma Hodgkin disease Gastric carcinoma

Kaposi sarcoma-associated herpesvirus	Kaposi sarcoma Multicentric Castleman disease Primary effusion lymphoma

promise in treating women suffering from HPV16-associated vulvar neoplasia.²⁵³

HPV-associated squamous cell carcinoma of the head and neck primarily occurs in the oropharynx and tonsils, and its incidence is rising rapidly. HPV-associated cancer appears to be less aggressive than classic head and neck cancer, which is associated with tobacco and alcohol use, p53 mutations, and low levels of the cdk inhibitor p16.⁴ HPV16 DNA is the predominant HPV type found in these cancers, and repression of HPV16 E6/E7 in head and neck cancer cell lines can inhibit their proliferation.³⁶⁹ Prophylactic VLP vaccines developed to prevent cervical cancer are likely to be effective in preventing head and neck cancer as well.

Epstein-Barr Virus

EBV virus is a ubiquitous human gammaherpesvirus that causes infectious mononucleosis and a variety of cancers including Burkitt lymphoma in Africa and nasopharyngeal cancer (NPC) in certain areas in Southeast Asia.⁴¹⁸ EBV also causes lymphoproliferative disease in individuals with congenital or acquired immunodeficiency, including central nervous system lymphomas in patients with acquired immunodeficiency syndrome (AIDS) and posttransplant lymphoproliferative disease in patients undergoing bone marrow or stem cell transplantation. EBV also appears to play a role in additional cancers including a substantial fraction of Hodgkin disease and some gastric cancers. EBV was the first human virus shown to cause tumors in nonhuman primates.⁴²⁷

A number of viral genes have been implicated in transformation by EBV including LMP1, which mimics an activated TNF receptor, and EBNA2, a transcription factor involved in lymphocyte immortalization. The LMP1 oncoprotein is often expressed in NPC specimens.⁴⁹ Because the EBV genome replicates as a plasmid in latently infected cells and tumors, the viral DNA replication factor EBNA1 is required for persistence of the viral genome. Studies in Burkitt lymphoma cell lines indicate that ongoing expression of EBV genes is required for the survival of these cells.²⁵² Further interesting features of Burkitt lymphoma include its association with malaria and with the consistent presence of chromosomal translocations in the tumor cells, which result in increased expression of the *c-Myc* proto-oncogene by fusing it to regulatory elements of immunoglobulin genes.

Kaposi Sarcoma Herpesvirus

KSHV, also known as human herpesvirus type 8 (HHV-8), is associated with Kaposi Sarcoma (KS), a systemic disease affecting multiple cell types and organs including the skin, with a prominent vascular endothelial component.³ In fact, the KSHV genome was first identified by molecular cloning from KS.⁶⁶ Unlike many other tumors, KS lesions are not monoclonal and display features consistent with paracrine signaling, and cells derived from them often lack properties of transformed cells.

KS, previously a very rare disease, is associated with immunosuppression and appeared in an aggressive form in a relatively high proportion of AIDS patients.¹⁴⁶ In fact, KS was the most common cause of cancer death in this population, but its incidence dropped dramatically with the use of highly active antiretroviral therapy (HAART) for HIV infection. However, because HIV-infected individuals on HAART are now surviving longer, the number of patients with KS and other

HIV-associated cancers may increase in the future. KSHV is also associated with primary effusion lymphoma and some cases of multicentric Castleman disease, a polyclonal lymphoid malignancy. The KSHV genome contains numerous homologs of cellular genes implicated in growth control and evasion of the host cell innate and adaptive immune response, but the pathogenesis of KS and other KSHV-associated cancer is undoubtedly complex and poorly understood.³²⁸

A number of drugs in clinical use inhibit herpesvirus DNA replication. The appearance of new KS lesions in AIDS patients was significantly suppressed by treatment with ganciclovir, a modified nucleoside that is phosphorylated by KSHV thymidine kinase and inhibits the viral DNA polymerase.^{61,301} This finding generates optimism that antiviral drugs have a role in the prevention and treatment of virally induced cancer.

Human T-Cell Leukemia Virus

HTLV-I was the first retrovirus implicated in human disease. Approximately 20 million people are infected with HTLV-I worldwide, with high endemic areas in Latin America, the Caribbean, Africa, and Japan. Infection is associated with adult T-cell leukemia/lymphoma (ATL), a relatively rare tumor, as well as some neurologic diseases.^{178,360,509} ATL typically arises decades after infection and occurs in only a small fraction of infected individuals. As described earlier, Tax protein appears to play a role in latently transforming T lymphocytes. It has multiple effects on transcription of cellular genes, and it affects a variety of other cellular processes as well.^{364,434} Despite the presence of *Tax*, ATL takes many years to develop. An explanation for the long latency of ATL could be that HTLV-I establishes a pool of T lymphocytes with enhanced proliferative potential, but that additional events (likely nonviral), such as accumulation of cellular mutations, are required for development of leukemia. The Tax protein is often not expressed in end-stage ATLs.²⁴⁵ This may reflect immunological selection against continued expression of this viral protein as the tumors progress. ATLs do express another viral protein, HBZ, encoded by an mRNA from the opposite strand of viral DNA.^{173,305} HBZ may contribute to the late stage of tumorigenesis (including down-regulation of Tax expression), while Tax may be involved in early preleukemic steps.²⁴⁵

Hepatitis B Virus

HBV infects more than 1 billion people worldwide and is associated with acute and chronic hepatitis, as well as with the majority of hepatocellular carcinoma (HCC).²¹ Although HBV contains a DNA genome, it undergoes an unusual replication cycle that involves RNA replicative intermediates.⁴⁵² Unlike the other DNA tumor viruses, HBV does not contain well-defined oncogenes, although the X gene has been implicated in cell transformation and tumorigenesis in transgenic mice.^{119,431} X affects cellular gene expression and may interfere with p53 function.¹⁵²

In some HBV-infected individuals (particularly those infected as infants), infection becomes persistent. Over time, persistent infection can lead to chronic liver damage (chronic active hepatitis [CAH]), which has a significant likelihood of progressing to HCC. In individuals with CAH, the liver injury caused by HBV replication and the resulting inflammation and rounds of hepatocyte proliferation and mutagenesis during liver regeneration are thought to cause the accumulation

of cellular mutations that lead to cancer formation. Reactive oxygen species produced by inflammatory cells recruited to sites of liver injury are also likely to cause DNA damage and mutagenesis. Moreover, segments of the HBV genome can show monoclonal integration patterns in HCC, raising the possibility that the viral genome also plays a *cis*-acting role in hepatic carcinogenesis.¹⁵¹ A recombinant HBV subunit vaccine has been deployed for decades and is reducing the incidence of HBV-mediated HCC.⁶⁵

Hepatitis C Virus

HCV is an RNA-containing virus of the *Flavivirus* family. HCV causes viral hepatitis and HCC and is also associated with non-Hodgkin B-cell lymphoma.^{82,332,355,394} HCV lacks a clearly defined viral oncogene, but HCV structural genes have transforming activity in various assays.^{282,321,433} Like HBV, HCV can establish persistent infections and CAH, leading to HCC. The carcinogenic potential of HCV is thought to derive primarily from its cytolytic activity in hepatocytes and the resulting inflammation and regeneration. However, unlike HBV, whose genome is relatively stable, even in a single infected individual the HCV genome is highly variable and constitutes a swarm of closely related viral variants, complicating attempts to develop an effective HCV vaccine. There are reports that successful antiviral treatment of HCV infection can also provide benefit for HCV-associated lymphomas.²¹⁵

Retroviral Oncogenesis in Human Gene Therapy Trials

Because retroviruses can stably deliver genes into host cell DNA, they have been used as gene transfer vectors in clinical trials to correct inherited genetic defects, most notably of the hematopoietic system.³³⁶ In one trial, an MuLV-based vector expressing the cytokine receptor common γ -chain was used to treat patients with X-linked severe combined immunodeficiency (X-SCID).²⁰¹ In this trial, hematopoietic progenitor cells from X-SCID patients were transduced with the vector *ex vivo* and then infused back into the same individuals. This approach corrected the SCID defect, but several of the treated individuals subsequently developed T-cell lymphoma.²⁰¹ Molecular analysis of the lymphomas revealed that the retroviral gene transfer vector caused insertional activation of the LMO2 proto-oncogene, as well as of other proto-oncogenes. Vector-induced malignancies or premalignant conditions have also arisen in similar trials for correction of chronic granulomatous disease and Wiskott-Aldrich syndrome.^{46,270,442} These findings raise cautions about the use of retroviral vectors for gene correction in humans.

In response to these findings, second- and third-generation retroviral vectors have been developed for human gene transfer. The enhancer sequences have been removed from the upstream LTR of the vector to generate a vector that has inactive LTRs after reverse transcription (a self-inactivating or SIN vector).⁵¹¹ The absence of functional viral enhancers in the transduced cells is designed to reduce the likelihood of insertional activation of cellular proto-oncogenes. A second approach has been to use retroviral vectors based on lentiviruses such as HIV-1, because lentiviruses have not been shown to induce cancer. Moreover, while MuLV has a preference for integration near the transcription start sites of genes (and thus may more efficiently activate adjacent genes), HIV-1 tends to integrate within the bodies of genes.^{315,409} A recent human clinical trial

to correct β -thalassemia employed an HIV-1-based SIN vector expressing human β -globin.⁶² In the first treated patient, the clinical symptoms of thalassemia were relieved, but there was an expansion of a clone of cells where the vector was inserted into the gene for HMG2A, which is overexpressed in certain malignancies. Molecular analysis of the integration site in these cells demonstrated that insertion of the provirus truncated the 3' noncoding region of HMG2A mRNA, resulting in removal of binding sequences for a regulatory miRNA and up-regulation of HMG2A mRNA. This is reminiscent of tumors in SL3-3 MuLV-induced T-lymphomas, where *gfi-1* was activated by removal of miRNA binding sequences from the mRNA.¹⁰⁰

Additional Viruses Implicated in Human Cancer

In addition to the six viruses firmly implicated in naturally occurring cancer, it is likely that additional viruses will be shown to be involved in cancer causation in humans, particularly for cancers associated with immunosuppression. Rapid improvements in DNA sequencing technology suggest that sequencing-based efforts are likely to be the prime method of detecting new candidate tumor viruses, as they were in the identification of KSHV and MCV (see next paragraph). Rigorous genetic, cell biological, and epidemiologic studies must be performed to confirm the role of any new candidates in human carcinogenesis.

The next virus likely to be recognized as a human tumor virus is Merkel cell polyomavirus (MCV). Merkel cell carcinoma is a rare but aggressive tumor of neuroendocrine cells in the skin, and it is often associated with sunlight exposure and immunosuppression. Through extensive sequencing of Merkel cell carcinoma RNA, in 2008 Feng et al.¹⁵⁴ identified sequences that were homologous to known polyomaviruses. Further analysis showed that up to 80% of Merkel cell carcinomas worldwide contain an intact, integrated polyomavirus genome, designated MCV. Like all known polyomaviruses, the MCV genome encodes LT that binds Rb family members and *sT* that binds PP2A. Tumors contain monoclonal integrations of MCV DNA in the cellular genome that disrupt the DNA replication activity of LT but leave the Rb binding activity intact,⁴²⁹ providing a plausible mechanism of tumor suppressor inactivation and cell transformation. Recent experiments indicate that Merkel cell carcinoma cell lines require MCV early region expression for continued proliferation²¹⁷ and that *sT* can transform rodent cells in culture. Taken together, these results provide strong evidence that MCV is the seventh human tumor virus. Similar to other oncogenic human DNA viruses, MCV infection appears to be fairly common,²⁵¹ even though Merkel cell cancers are rare.

SV40 itself has been implicated in a number of human cancers, including non-Hodgkin lymphoma, mesothelioma, and childhood brain tumors.¹⁷⁰ However, the evidence in support of these claims, and even of the conclusion that SV40 infection can occur in humans, remains controversial. Two pathogenic human polyomaviruses closely related to SV40, JC virus and BK virus, have also been implicated in human cancer, but the evidence for oncogenic activity in humans is inconclusive.

A retroviral genome closely related to MuLV genomes has been detected in human prostate carcinoma DNA and named xenotropic murine leukemia virus-related virus (XMRV). XMRV DNA was originally found in patients with hereditary prostate cancer, and the viral genome was detected in stromal

cells, not epithelial tumor cells.⁴⁷⁰ Some subsequent reports have detected XMRV DNA and proteins in prostate cancer specimens, but the association of the virus with the hereditary form of prostate cancer and its restriction to stromal cells has not been confirmed.^{157,404} Other groups have failed to detect any association of XMRV with prostate cancer. Recent molecular studies suggest that XMRV was generated by recombination between two endogenous MuLV-related retroviruses during passage of a human prostate cancer in nude mice.³⁴⁴ As a consequence, the prostate cancer cell 22Rv.1 produces high amounts of XMRV, which replicates efficiently in certain human prostate cancer cell lines and appears to have been detected as a contaminant during surveys of prostate cancer tissues by highly sensitive PCR amplification techniques. Viruses related to MMTV have been suggested to play a role in the etiology of human breast cancer, but convincing candidate viruses have not yet emerged.

The foregoing discussion assumes that tumor virus gene products persist in tumor cells. If a virus can cause cancer through a true “hit-and-run” mechanism, there may be many more human tumor viruses than are currently recognized.

Finally, although HIV is not regarded as a tumor virus, the immunosuppression caused by HIV plays an important role in the genesis of many virally induced tumors. AIDS is associated with increased frequencies of many of the virus-associated human cancers (e.g., HPV-associated cancer of the cervix and anus, EBV-associated lymphomas, and Kaposi sarcoma). This suggests that the increased cancer incidence in AIDS patients results from reduced immunological control of the oncogenic virus. However, the incidence of some nonviral cancers is also elevated in individuals with AIDS. Improved prevention and control of HIV infection will reduce worldwide cancer prevalence.

WHY DO VIRUSES TRANSFORM CELLS?

The preceding sections describe how viruses transform cells. But why do so many diverse viruses transform cells and cause tumors? Evolution selects for the ability of viruses to replicate, avoid host cell defenses, and spread to new hosts. Many viruses accomplish these tasks without displaying transforming or tumor-forming activity, so transforming activity *per se* is not essential for virus replication.

Retrovirus transformation is incidental to virus replication. The absence of oncogenes in the replication-competent non-acute retroviruses demonstrates that these genes are not required for virus replication. Rather, the appearance of monoclonal tumors in animals many months after infection indicates that tumorigenic transformation by these viruses is an exceedingly rare event at the cellular level. This conclusion is supported by the inability of these viruses to transform cultured cells. It is only because of the huge number of infected cells in animals and the dramatic consequences of *in vivo* transformation, namely, tumor formation, that these events are even observed by scientists and studied. Presumably, proviruses integrate near many cellular genes, but the vast majority of these integration events do not provide a growth advantage to the cells, and therefore they are not detected. For the acutely transforming retroviruses, oncogenes are acquired from the host cell genome extremely infrequently during virus propagation. But once incorporated in an active form into the viral genome, the transduced gene is introduced into every newly infected cell and is a potent and

rapidly acting carcinogen, allowing scientists to capture these viruses. Tumor-forming activity confers no replication advantage to these viruses, and in fact the acquisition of an oncogene is in almost all cases associated with virus replication defects.

The peculiar lifestyle of retroviruses, involving integrated proviruses that stably persist in infected cells, explains why these viruses are unique among RNA viruses in having transforming potential in cultured cells, because the provirus allows the sustained expression of the viral oncogene or acts *in cis* to regulate the expression of cellular proto-oncogenes or tumor suppressor genes.

DNA tumor virus oncogenes typically are essential, intrinsic viral genes. The biochemical activities of the proteins encoded by these genes were selected during virus evolution for their roles in virus replication and persistence, not for their ability to transform cells. In order for viruses to synthesize the large amounts of viral DNA needed to sustain a productive infection, up to 100,000 or more progeny genomes per infected cell, the cell must be reprogrammed into a DNA replication factory to provide an abundant supply of DNA polymerases and other replication factors. Most cells are resting and not able to support high-level DNA replication when initially exposed to a virus. Therefore, the virus must stimulate the cell to enter S phase to generate a cellular environment conducive to viral DNA replication. What better way to generate this state than to exploit the intrinsic cellular machinery that controls cell cycle progression? Thus, it is no accident that DNA virus oncoproteins stimulate cell proliferation. And when virus replication is aborted, in non-permissive cells for example, and the viral genome undergoes rare recombination events to integrate into cellular DNA, the ongoing proliferative stimulus may result in cell transformation or tumor formation. According to this view, transformation by DNA viruses is an accidental byproduct of their need to drive the cell into S phase for viral DNA replication. Consistent with this hypothesis is the observation that parvoviruses, which do not stimulate S phase and can only replicate in cells induced by other means to enter the cell cycle, are one of the few DNA virus groups devoid of transforming activity.

This aspect of viral oncogene action can be seen clearly with the E7 protein of HPV, because the cells undergoing various responses in stratified squamous epithelia are physically separated. HPV initially infects basal epithelial cells. Normally, when basal cells divide and migrate away from the basement membrane, they undergo a process of terminal differentiation and growth arrest, which is incompatible with vegetative viral DNA replication. However, high-level viral DNA replication must be able to take place in the suprabasal cells because keratinocyte differentiation is required for the virus life cycle to proceed. Therefore, the viral E7 protein inactivates the Rb pathway in suprabasal cells to maintain the DNA replication machinery in an active state without preventing keratinocyte differentiation.⁷⁶ The ability of the E7 protein to inhibit the activity of p21^{WAF1}, which is implicated in keratinocyte differentiation, may assist in this process.^{165,242}

Another aspect of viral tumorigenesis is suggested by the presence of immune evasion genes in the larger DNA viruses such as the herpesviruses. This model posits that transforming activity and tumorigenesis are indirect consequences of viral countermeasures to defense mechanisms erected by the host cell.³¹⁷ Upon initial confrontation with a virus, and even in response to latent infection, cells mobilize innate immune

signaling pathways to block virus replication. In some cases, these pathways activate tumor suppressor pathways or interferon signaling, resulting in growth arrest or apoptosis, which restricts virus replication or spread. The transforming proteins of some viruses may have evolved to neutralize tumor suppressor pathways and thereby circumvent these cell defenses and other innate immune pathways. By removing these blocks to virus propagation, the blocks to cell proliferation are removed as well. Virus genes that inhibit these host defenses thus exert a proliferative and eventually a transforming effect on the cells.

Neither transforming activity nor tumorigenicity is required for replication of RNA and DNA tumor viruses, and these activities have not been directly selected for during evolution. Rather, transforming activity is an accident or at most an unintended consequence of the complex biochemistry of viral genome integration, replication, and persistence. From the scientific and medical point of view, we are the beneficiary of these accidents, because they have generated a set of biological reagents, the viruses themselves, which have provided unprecedented insights into such fundamental cellular and pathologic processes as signal transduction, cell cycle control, and above all carcinogenesis. The dependence of nonviral tumorigenesis on the same pathways mobilized by tumor viruses emphasizes the central role of the regulatory pathways targeted by these viruses and highlights the value of tumor viruses as uniquely powerful probes of cell function.

Conclusion

The innate immune system provides a universal form of host protection from infectious diseases. It detects the presence of pathogens using several recognition strategies. The best-characterized innate microbial sensing mechanism is based on pattern recognition receptors (PRRs). These receptors detect conserved microbial structures shared by entire classes of microorganisms. The targets of PRRs are commonly products of metabolic pathways unique to a particular class of microbes, such as lipopolysaccharide in the case of Gram-negative bacteria. In the case of viral pathogens, however, all viral molecular constituents are produced in the host cell. Consequently, the major targets of innate immune recognition are viral nucleic acids. Whenever possible, the innate immune system detects structural features of viral RNA and DNA that are distinct from the host nucleic acid. These include long double-stranded RNA, RNAs containing 5'-triphosphate, and unmethylated CpG motifs in viral DNA genomes. Detection of these structural features, however, is insufficient to reliably distinguish the host and viral nucleic acids. Therefore, additional factors help to determine their origin. For example, viral but not host nucleic acids are normally found in the endolysosomes and viral but not host DNA is present in the cytosol. Innate immune sensors of viral RNA and DNA are present in these locations, where they can be triggered to activate the antiviral responses. In addition to pattern recognition, viral pathogens might be detected indirectly, through alteration in normal cellular processes, such as acute decline in host protein synthesis, altered activity of ion channels, or ER stress. These forms of recognition are still incompletely understood and remain to be fully characterized in future studies.

Detection of viral pathogens by the innate immune system has two major consequences: first, it leads to the induction of the innate antiviral mechanisms, most of which are mediated primarily by type-I interferons (IFNs). Second, it leads to the activation of the adaptive immune response that can provide a more directed, antigen-specific, and long-lasting antiviral immunity. The main host defense strategy against viral pathogens is the elimination of the infected cells. This can be achieved by cell-intrinsic mechanisms that are induced by type-I IFNs and operate in the infected cells, or with the help of cytotoxic lymphocytes: natural killer (NK) cells and CD8 T cells. Another important host defense mechanism is the blockade of viral entry into the host cells. This is primarily a function of neutralizing antibodies. Many additional mechanisms exist that interfere with viral replication, gene expression, virion assembly, and exit from the infected cells. The relative contribution of these defense mechanisms varies depending on the virus and host. Detailed knowledge of the specific antiviral defense mechanisms is difficult to establish due in large part to a high degree of redundancy between different mechanisms.

In this chapter, we will focus on the better-characterized viral sensing mechanisms of the innate immune system and discuss the major defense mechanisms utilized in mammalian hosts.

SENSING VIRAL INFECTIONS

Viral Sensing Through Pattern Recognition Receptors

The mammalian immune system detects the presence of viruses through multiple mechanisms. The best understood mechanisms involve various PRRs. Most common molecular patterns associated with virus infection are the features associated with viral nucleic acids. Innate immune recognition can be cell intrinsic or cell extrinsic, depending on whether it is mediated by infected or non-infected cells. Cell-intrinsic innate immune recognition is mediated by cytosolic sensors, including the NOD-like receptors (NLRs) and RIG-I-like receptors (RLRs). Activation of these receptors generally occurs in infected cells. Accordingly, PRRs involved in cell-intrinsic recognition are broadly expressed because viral pathogens target a variety of cell types for replication. In contrast, cell-extrinsic innate immune recognition is mediated by transmembrane receptors (including Toll-like receptors (TLRs) and C-type lectins [CLRs]); their activation does not require the cells expressing these receptors to be infected. Cell-extrinsic recognition is mainly mediated by specialized cells of the immune system, such as the plasmacytoid dendritic cell (pDC), macrophage, and dendritic cell (DC).

PRRs involved in microbial recognition have modular structures and share several structurally related domains for innate recognition, multimerization, interaction with adaptor molecules, and signaling (Fig. 8.1).

CELL-AUTONOMOUS VIRUS RECOGNITION

RIG-I-Like Receptors (RLRs)

RNA viruses are recognized by the cytoplasmic RNA helicases, retinoic acid-inducible gene-I (RIG-I), and melanoma differentiation-associated gene 5 (MDA5).¹⁹⁸ The RIG-I-like

receptors (RLRs) are expressed by most cell types, and both RIG-I and MDA5 recognize viral RNA through their helicase domains. RIG-I also contains the repressor domain (RD) at its C-terminus, which inhibits the activation of RIG-I at steady state. Binding to viral RNA catalyzes a conformational rearrangement, which exposes a caspase activation and recruitment domain (CARD) to initiate antiviral signaling^{152,199} (Fig. 8.1). Both RIG-I and MDA5 utilize a common adaptor molecule called mitochondria antiviral signaling protein (MAVS)¹⁶²—also known as IPS-1,⁹³ Cardif,¹²⁷ or VISA¹⁹⁴—that localizes to the mitochondrial membrane¹⁶² and to the peroxisomes.⁴⁷ MAVS activates two protein kinase complexes, one consisting of FADD and caspases 8/10¹⁷⁵ and the other containing TANK and NAP1¹⁵⁵ (Fig. 8.2). The former activates the IKK α /IKK β /IKK γ complex while the latter activates the TBK1-IKKi complex, leading to the activation and nuclear translocation of transcription factors NF- κ B and IRF3, respectively. In addition, the TRAF6-dependent pathway involving MEKK1 is essential to activate the MAP kinase and NF- κ B pathways.²⁰¹ Despite similarity in overall structure and signaling mechanisms, RIG-I and MDA5 have important differences in their mechanisms of activation. For example, RIG-I but not MDA5 requires ubiquitination by E3 ligase TRIM25 for its activity.⁵⁸ Additional differences in the function of RIG-I and MDA5 likely exist and may reflect distinct features of viral pathogens that they recognize.

Analysis of animals deficient in the RLRs revealed important and distinct roles for these sensors in innate immunity. These molecules cumulatively provide the host with the ability to recognize a large group of viral pathogens in infected cells and mediate a critical aspect of innate antiviral defense.

RIG-I

RIG-I consists of two N-terminal CARDS, a central DExH box RNA helicase/adenosine triphosphatase (ATPase) domain, and a C-terminal regulatory domain (RD) (Fig. 8.1). RIG-I functions as a critical PRR for a number of viruses including Sendai virus (SeV), vesicular stomatitis virus (VSV), influenza, hepatitis C virus, Japanese encephalitis virus, as well as small RNA encoded by the DNA virus, Epstein-Barr virus.⁹² RIG-I

FIGURE 8.1. Domain structure of viral sensors and adaptor molecules. Pattern recognition molecules involved in viral sensing contain distinct domains, some of which are shared by different classes of receptors. These domains include: CARD, caspase activation and recruitment domain; DD, death domain; HIN200, hemopoietic IFN-inducible nuclear proteins is a 200-amino acid motif; LRR, leucine-rich repeat; NOD, nucleotide-binding oligomerization domain; Pro, proline-rich region; PYD, pyrin domain; caspase domain; TIR, toll/interleukin-1 receptor; TM, transmembrane region. Many of these domains can be used for homotypic oligomerization. Examples of molecular complexes are depicted for NLRP3 and AIM2 inflammasomes.

FIGURE 8.2. RIG-I and MDA-5 virus recognition pathways. In a virally infected cell, RNA structures that are unique to viruses are recognized by RIG-I and MDA-5. RIG-I detects ssRNA containing 5' triphosphate, while MDA-5 recognizes a long stretch of dsRNA. RNA binding to RLRs induces conformational changes, enabling their binding to MAVS adaptor protein expressed on the surface of mitochondria and peroxisomes. MAVS activates signaling to activate NF- κ B, MAP kinases, and IRF3, leading to target gene expression including IFN- β and cytokines. Type I IFNs increase the levels of RLRs in bystander cells, enabling robust antiviral signaling upon infection.

recognizes single-stranded (ssRNA) that contains 5' triphosphate end, but not 5' OH or a 5'-methylguanosine cap^{73,144} that is longer than 23 nucleotides¹²³ and contains a uridine- or adenosine-rich ribonucleotide sequence¹⁵³ (Fig. 8.2). RIG-I can also recognize double-stranded (dsRNA) in the absence of 5' triphosphate in some cases with a preference for shorter-length dsRNA compared to those recognized by MDA-5.⁹¹ Analysis of the central DExH box RNA helicase/ATPase domain of RIG-I revealed an ATP-powered dsRNA translocation activity. The CARD domains suppress translocation in the absence of 5'-triphosphate, and the activation by 5'-triphosphate triggers RIG-I to translocate preferentially on dsRNA *in cis*.¹³⁰ This ATPase activity is required for RIG-I signaling, indicating that RIG-I recognizes two distinct features of viral RNA simultaneously: triphosphate at the 5' end and dsRNA. RIG-I indeed selectively detects blunt, short, double-stranded 5'-triphosphate RNA, which is common in the panhandle region of ssRNA viral genomes.¹⁵⁷

MDA5

MDA5 serves as a sensor of picornaviruses and can be activated by cytosolic synthetic dsRNA, such as polyinosinic-polycytidylic acid (poly I:C).^{60,92} There appears to be some level of redundancy in RIG-I and MDA5 in recognition of certain viruses. Dengue virus and West Nile virus are recognized by both MDA5 and RIG-I; either of these sensors is sufficient to induce type I IFN production.¹¹⁵ Comparison of synthetic and viral dsRNA revealed that MDA-5 preferentially recognizes longer dsRNA that is at least 2 k bp in length, while RIG-I is activated by a wider range of dsRNA sizes (400 bp–4 kbp).⁹¹ Many viruses that replicate in the cytoplasm express their own 2'-O-methyltransferases to autonomously modify their messenger RNA (mRNA). Interestingly, infection with viruses deficient in 2'-O-methyltransferase leads to robust activation of MDA5, indicating that lack of ribose 2'-O-methylation is used as a signature of viral RNA for recognition by MDA5.²⁰⁵ Therefore, MDA5 likely recognizes large dsRNA structures lacking 2'-O-methylation generated in the cytosol during virus infection. Of note, 2'-O-methylation is also used by viruses to evade restriction by IFN-induced proteins with tetratricopeptide repeats (IFIT) proteins.^{36,205}

LGP2

The third member of the RLR family, laboratory of genetics and physiology 2 (LGP2), displays sequence homology to the helicase domains of RIG-I and MDA5. It lacks a CARD domain, however, and therefore has been proposed to serve as a negative regulator of both sensors. Overexpression studies indicated that LGP2 does not activate the production of type I IFNs on its own, but inhibits RIG-I- and MDA5-mediated signaling in a dose-dependent manner.^{98,149,200} Interestingly, studies of *lgp2* knockout mice indicated that LGP2 may play both positive and negative regulatory roles in MDA5- and RIG-I-mediated innate immunity.¹⁸⁹ This study found that the loss of *lgp2* augments type I IFN production in response to transfected poly I:C (MDA-5 agonist) or VSV infection (RIG-I agonist). In contrast, LGP2 is required for efficient antiviral responses following EMCV infection (MDA5 agonist). Therefore, LGP2 can serve as a positive or negative regulator of RLR signaling depending on the type of viral infection. The precise mechanism underlying the opposing functions of LGP2 is still unclear.

NOD-Like Receptors (NLRs)

NLRs comprise a large family of intracellular PRRs that regulates innate immunity in response to recognition of various PAMPs and stress signals.¹²⁵ The NLR family consists of multidomain proteins that contain a C-terminal LRR domain, a central NOD domain and an N-terminal effector domain. NLR proteins can be subdivided into three subfamilies depending on the structure of N-terminal domains: CARD-containing subfamily (NOD1, NOD2, NLRCs, CIITA), pyrin domain (PYD)-containing subfamily (NLRPs) (Fig. 8.1), and BIR domain-containing subgroup (NAIPs) (not shown). Both NOD and NLRP members contribute to antiviral defense. The PYD subfamily of NLRPs consists of 14 members. Although the functions of many of the NLRPs are largely unknown, several NLRPs play a key role in the activation of caspase-1 by forming a multiprotein complex known as the

FIGURE 8.3. Inflammasome activation by virus infection. Virus infection can lead to inflammasome activation through two separate pathways. NLRP3 inflammasome is activated upon infection by adenovirus or influenza virus. This pathway is initiated by membrane perturbation, K⁺ efflux, and reactive oxygen species (ROS). The second pathway involves AIM2, which is activated by dsDNA in the cytosol. Both NLRP3 and AIM2 form a complex with ASC and pro-caspase-1 (inflammasome), leading to the self-cleavage and activation of caspase-1. Pro-forms of IL-1 β and IL-18 induced by TLR signals are cleaved by activated caspase-1. Mature forms of these cytokines are then released to the extracellular space.

“inflammasome”¹²⁴ (Fig. 8.3). Caspase-1 is an essential mediator of inflammatory response through its capacity to cleave and generate active forms of IL-1 β and IL-18. IL-1 β and IL-18 are potent proinflammatory cytokines, as described below. Formation and secretion of mature IL-1 β and IL-18 require a two-step activation mechanism: first, transcriptional and translational upregulation of the pro-forms of these cytokines are induced by TLR signaling, and a second signal that leads to the proteolytic activation of caspase-1. The latter process is mediated by the inflammasome. Inflammasome complexes that are important in antiviral defense are described below.

NLRP3-ASC Inflammasome

NLRP3, also known as NALP3/Cryopyrin/CIAS1/PYPAF1,¹⁸¹ forms an ASC-dependent inflammasome (Fig. 8.3). The NLRP3 inflammasome can be activated by a variety of stimuli including endogenous signals from dying cells (uric acid), crystals (asbestos, silica, alum), as well as microbial signals such as whole bacteria, bacterial RNA, extracellular ATP, pore-forming toxins, or viral infections.¹²⁵ It is unclear whether microbial ligands can directly activate the NLRP3

inflammasome. Instead, the NLRP3 inflammasomes likely sense cellular stress such as disruption in membrane integrity and extracellular ATP released from stressed or damaged cells. Virus infection also results in the activation of inflammasomes. Both SeV and influenza virus activated the NLRP3 inflammasome in macrophages pulsed transiently with ATP (signal 2) *in vitro*.⁹⁰ DNA viruses such as adenovirus stimulate the NLRP3-ASC-caspase-1 inflammasomes *in vivo*.¹²⁹ However, inflammasomes are not activated by transfection of RNA, poly I:C, or infection with reovirus (dsRNA virus) or VSV (ssRNA virus),¹²⁹ indicating that viral RNAs are insufficient to trigger inflammasome activation. Influenza virus activates the inflammasome through the activity of the M2 ion channel.⁷⁹ The M2 channel of influenza A virus is a homotetrameric integral membrane protein that associates to form a highly specific proton channel,¹⁴⁵ and is essential for influenza A virus infection and replication.¹⁷⁹ Among other things, the M2 channel exports protons in the acidic trans-Golgi network (TGN) to neutralize the pH of the lumen of the TGN in order to prevent the premature maturation of hemagglutinin to its low-pH fusogenic form.³² Within influenza virus-infected cells, NLRP3 complex detects changes in ionic imbalance in the TGN to activate the inflammasomes. *In vivo*, NLRP3 deficiency resulted in increased susceptibility to high-dose flu challenge.^{4,180} In addition, after a sublethal dose of influenza infection, ASC-dependent inflammasome activation is required to elicit adaptive protective immunity to influenza virus, indicating the importance of NLRs in linking innate viral recognition to adaptive immunity.⁷⁸

AIM2-ASC Inflammasome

Not all inflammasomes are activated by NLRPs. Recent studies showed that AIM2 couples cytosolic dsDNA recognition to ASC-caspase-1 inflammasome.^{25,53,72,148} AIM2 is an HIN200 family of protein that contains a dsDNA binding domain (HIN domain) and the PYD domain, which promotes interaction with the PYD domain of ASC (Fig. 8.1). AIM2 recognizes dsDNA in the cytosol and induces oligomerization of ASC and caspase-1, leading to activation of caspase-1 and cleavage of pro-forms of cytokines including IL-1 β , IL-18, and IL-33 (Fig. 8.3). Vaccinia virus, which contains a dsDNA genome, was shown to require AIM2 for recognition and activation of caspase-1 inflammasomes.⁷² It is interesting to note that different classes of dsDNA viruses are recognized by NLRP3 (adenovirus) or AIM2 (vaccinia virus) for inflammasome activation. This likely depends on both the accessibility of the dsDNA genome to intracellular sensors and the viral-induced cellular stress responses. While cytosolic dsDNA can bind to AIM2 directly and activate inflammasomes, how and where exactly NLRP3 becomes activated by dsDNA viruses is yet to be determined.

p202

Mouse HIN200 protein, p202, is a negative regulator of the AIM2 inflammasome.¹⁴⁸ No orthologs of p202 have been found in humans. p202 contains two HIN domains but no PYD domain, and binds specifically to dsDNA. Unlike AIM2, p202 cannot bind ASC and therefore appears to function as an inhibitor of AIM2, presumably by limiting its access to DNA.

Cytosolic DNA Sensors

The existence of a cytoplasmic DNA sensing molecule leading to type I IFN production was suggested from studies of

infection by DNA viruses and bacteria.^{82,170} It is now clear that there are likely multiple sensors that recognize distinct types of DNA. These DNAs include DNA from viruses, bacteria, apoptotic host cells, and synthetic B-form DNAs—particularly poly(dA:dT) and interferon stimulatory DNA (ISD). ISDs are dsDNA containing >25 base-pair oligonucleotides, which in sequence-independent manner, trigger stimulation of type I IFNs through a pathway involving TBK1 and IRF3, but not MAVS.¹⁷⁰ Interestingly, ISD does not engage NK- κ B or MAPK pathways, thus activating only IRF3-induced pathways. ISD recognition pathway exists only in primary cells but is lost from transformed cells.¹⁷⁰ However, the sensor for ISD still remains to be identified. TREX1, an exonuclease, was identified to be a negative regulator of ISD pathway by inhibiting excess accumulation of DNA products from endogenous retroelements.¹⁶⁹ TREX1-deficient humans and mice suffer from autoimmune disease due to hyperstimulation of ISD pathway. TREX1 is also involved in degrading nonproductive RT products generated during HIV-1 infection, enabling HIV-1 to remain undetected by the ISD sensor.¹⁹⁵

In contrast, B-form DNA—or poly(dA-dT)·poly(dT-dA) dsDNA—triggers type I IFNs via IRF3 and NK- κ B, suggesting that this form of DNA triggers a separate sensor from ISD.⁸¹ The sensor(s) for cytosolic DNA remained elusive until recently. First, a molecule called DAI (also known as DLM-1/ZBP1) was identified as a candidate intracellular DNA sensing molecule.¹⁷⁶ IFN induction following poly(dA-dT)·poly(dT-dA) DNA treatment was abrogated by a small interfering RNA (siRNA) directed against DAI, suggesting that DAI is a critical cytoplasmic DNA sensor.¹⁷⁶ However, DAI is not the sole sensor of DNA in the cytosol, as DAI-knockout mice still responded to B-DNA or plasmid DNA.⁸³ More recent studies showed that poly(dA-dT)·poly(dT-dA) DNA is recognized by RIG-I upon transcription by RNA polymerase III (Pol III).^{1,30} Pol III synthesizes 5'-triphosphate RNA using AT-rich dsDNA as a template, generating an RIG-I agonist in the cytosol. Therefore, RIG-I is the sensor for cytosolic poly(dA-dT)·poly(dT-dA) dsDNA upon transcription by Pol III. In addition to the indirect sensing of poly(dA-dT)·poly(dT-dA) by RIG-I, IFI16, a PYHIN protein, can bind to poly(dA-dT)·poly(dT-dA), and knockdown of IFI16 expression led to reduction in IFN- β production.¹⁸⁶

Cyclophilin A

While most pattern recognition of virus infection involves detection of nucleic acids, there are few exceptions in which viral protein serves as a signature for viral infection. Cyclophilin A is a peptidylprolyl isomerase that can catalyze *cis/trans* isomerization of X-Proline epitopes on target proteins. Innate response to HIV-1 in DCs depends on interaction between the newly synthesized HIV-1 capsid and cellular cyclophilin A, leading to activation of type I IFNs through IRF-3-dependent mechanisms.¹²² Human DCs, but not CD4 T cells, have intrinsic machinery for responding to HIV-1 infection through cyclophilin A. However, infected humans are unable to utilize the cyclophilin A-dependent pathway of IFN induction against HIV-1 infection because DCs are resistant to HIV-1 infection. In addition, cyclophilin A is also known to be incorporated into the HIV-1 virions by binding to capsid protein. Virions lacking cyclophilin A possess normal morphology and can penetrate host cells, but are defective in the reverse transcription of viral RNA.²² Therefore, HIV-1 utilizes cyclophilin

A for its infectivity, and renders cyclophilin A useless in antiviral defense by avoiding infection in the relevant cell type.

CELL-EXTRINSIC VIRUS RECOGNITION

Toll-Like Receptors (TLRs)

TLRs are the best characterized members of the PRR family, which recognize evolutionarily conserved molecular patterns associated with a large variety of microorganisms.⁸⁷ There are 11 functional TLRs in mice (TLR1–7, 9, 11–13) and 10 functional TLRs in humans (TLR1–10). All TLRs are type I transmembrane proteins with ectodomains containing leucine rich repeat (LRR) that mediate the recognition of PAMPs. Some TLRs recognize bacterial, fungal, and protozoan pathogens, while others are dedicated for viral recognition.¹⁷⁷ This chapter will focus on the TLRs that recognize viral pathogens.

The transmembrane domains of TLRs dictate the localization of the receptor, and the cytosolic domain contains the toll/interleukin-1 receptor (TIR) domain, which binds to adaptor proteins and ultimately leads to expression of a variety of genes.² TLR activation, following virus detection, catalyzes a complex signaling cascade that bifurcates into two main pathways, culminating in the synthesis of proinflammatory cytokines (NF- κ B-dependent) and antiviral cytokines, type I interferons (IFNs) (IRF-dependent). In addition, TLR signaling results in the activation of the mitogen-activated protein kinases (MAPKs) (see Fig. 8.5). Type I IFNs in turn induce a battery of genes that directly suppress viral replication. Other cytokines and chemokines efficiently recruit immune cells to sites of virus infection. In particular, TLR recognition by DCs, the most potent antigen-presenting cells, enables their activation and antigen-presenting function, effectively linking innate recognition to the induction of adaptive immunity.⁸⁶

TLRs are distributed on specific subcellular locations and are specifically expressed by different cell types. TLRs can be categorized into two major types: those that are expressed on the cell surface (TLR1, 2, 4, 5, 6, 11, and 12) and those that are expressed in the endolysosomes (TLR3, 7, 8, and 9). Although virus–TLR interaction can occur with both types of TLRs, many of the virus interactions with surface TLRs represent viral invasion mechanism (beneficial to the virus) rather than PAMP recognition by TLRs (beneficial to the host) (see discussion under Virus Manipulation of Innate Immunity). In this section, we will discuss the latter type of TLR-virus PAMP recognition leading to antiviral defense.

Viruses are recognized by a group of TLRs that reside in the endosomal membrane—namely, TLR3, 7, 8, and 9—where they can gain access to viral nucleic acids upon endocytosis of virions. A major advantage of this strategy of viral recognition is that the viral sensing and subsequent induction of type I IFN genes are not subjected to viral evasion mechanisms. In addition, since all viruses contain genomes consisting of RNA or DNA, such molecular patterns can be surveyed by a very limited number of receptors. These endosomal TLRs require trafficking by the endoplasmic reticulum (ER) membrane protein, UNC-93B.^{24,174} UNC-93B physically interacts with TLR3, 7, and 9 via the transmembrane domain,²⁴ and transports these TLRs from the ER to the endosome (Fig. 8.4). Mutations in the *Unc93b1* gene were found in two patients with severe HSV encephalitis,²⁶ indicating the importance of transport of endosomal TLRs via

FIGURE 8.4. Endosomal TLR trafficking and processing. Endosomal TLRs, TLR3, TLR7, and TLR9, are synthesized in the ER, transported through Golgi, and are sorted into endosomes. UNC93B is an ER-resident protein, which facilitates TLR transport to the endolysosomes. Once in the endosomes, TLR3, 7, and 9 undergo proteolytic cleavage by proteases, which makes these receptors competent for signaling.

UNC93B in antiviral defense. Upon arrival in the endosomal compartment, these TLRs undergo processing by endosomal proteases. While full-length and cleaved forms of TLR9 are capable of binding ligands, only the processed form recruits MyD88 upon activation.^{52,140} The ectodomain of TLR9, and likely TLR3 and TLR7,⁵² must first be cleaved in the endolysosomes by cathepsins in order to become competent for signaling (Fig. 8.4). Dependence of TLR9 activation on proteolytic processing in the endolysosomes ensures that aberrant activation of TLR9 from cell surface (for example, upon recognition of self DNA) is avoided.

TLR3

TLR3 is expressed by a variety of cells in human and mice, including conventional DCs, B cells, fibroblasts, and epithelial cells but not in plasmacytoid DCs (pDCs). Upon PAMP recognition, TLR3 recruits TRIF via its TIR domain (Fig. 8.5). TRIF is responsible for activation of both NF- κ B and IRF3, leading to proinflammatory cytokines and type I IFN gene expression, respectively. TRIF binds to TRAF6, which is a RING-domain E3 ubiquitin ligase capable of polyubiquitinating TRAF6 and IKK γ . Ubiquitinated TRAF6 and IKK γ recruit TAK1 complex (consisting of TAK1 and TAB proteins), leading to the activation of MAPK. TRIF also binds to receptor-interacting protein (RIP)1 to initiate NF- κ B activation. To activate the type I IFN genes, TRIF also recruits TRAF3, which engages TBK1 and subsequent activation of IRF3. IRF-3 translocates to the nucleus and binds to promoters of type I IFN genes.

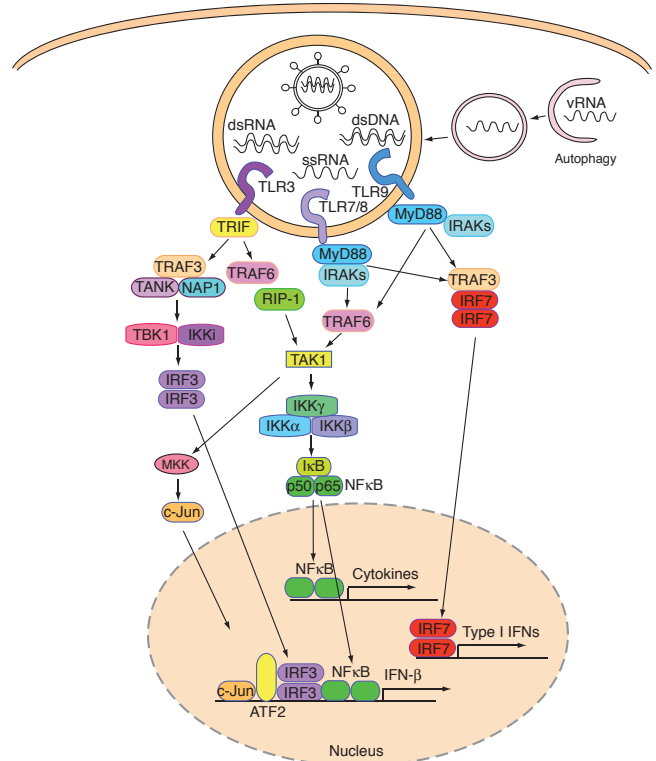

FIGURE 8.5. Endosomal TLR virus recognition and signaling. Viruses or virus-infected cells are endocytosed, and signatures of virus infection become accessible to TLRs upon digestion of membranes and nucleocapsid. TLR3 recognizes dsRNA, TLR7 and TLR8 recognize ssRNA, and TLR9 recognizes DNA. In addition, autophagy delivers TLR7 ligand (cytosolic viral replication intermediate) by fusion with the endosomes containing TLR7. Proteolytically activated TLRs in the endosomes recruit adaptor proteins and induce downstream signaling to activate a variety of transcription factors. IRF3 in combination with NF- κ B, c-Jun, and ATF2 bind to the promoter and induce IFN- β expression. IRF7 homodimer binds to promoter regions of *IFN- α* genes and induces IFN- α expression. In addition, NF- κ B activates transcription of a large number of genes, including cytokines.

dsRNA intermediates are produced during the replication cycle of most RNA viruses (except for retroviruses). DNA viruses also produce dsRNA by convergent transcription of their genomes.¹⁹³ It has long been known that dsRNA triggers IFN production. The first TLR implicated in viral nucleic acid recognition was TLR3.³ TLR3 responds to the artificial dsRNA mimic, poly I:C, when it is provided extracellularly.^{60,92} However, evidence supporting TLR3-mediated recognition of authentic viral replication intermediates remains elusive, possibly due to overlapping recognition pathways that can compensate for the loss of TLR3. TLR3 may be involved in recognizing virus-produced dsRNA in the context of phagocytized apoptotic cells.¹⁵⁹ Humans with dominant negative mutations in the *tlr3* gene suffer from neonatal herpes infection,²⁰² indicating the importance of this receptor in protection against HSV-1 in the CNS.

TLR7/8

In humans, TLR7 is expressed in plasmacytoid DCs and B cells, while TLR8 is expressed by myeloid DCs and monocytes. In

mice, TLR7 is expressed by pDCs, conventional DCs (except for CD8 α^+ DCs), and B cells. The function of the mouse TLR8 is still poorly understood. However TLR8-deficient mice develop autoimmunity due to hyperstimulation of TLR7.³⁹ TLR7, 8, and 9 are all expressed in the endosomes and share similar signaling pathways. Upon engagement, these receptors recruit MyD88 via the TIR domain. MyD88 subsequently interacts with the death domain of several IRAK proteins to induce both NF- κ B and IRF7 activation. IRAK4 is required for activation of NF- κ B pathway by interacting with TRAF6, which in turn activates the TAK1 complex, leading to activation of NF- κ B and MAPK pathways (Fig. 8.5). NF- κ B activation follows the recruitment of IRF5 to the MyD88 complex. On the other hand, MyD88 also recruits IRF7, which forms a signaling complex with IRAK4 and TRAF6. TRAF3 also binds MyD88 and IRAK1 to induce IRF7 activation. Unlike TLR3, TLR7 and 9 utilize IRF7 and not IRF3 for activation of type I IFN genes in pDCs. Interestingly, in conventional DCs, TLR7 and 9 utilize MyD88 and IRF1 to induce IFN- β but not IFN- α genes.¹⁴³

TLR7 and 8 recognize ssRNA and induce innate immune responses to ssRNA viruses. TLR7 is required for type I IFN and cytokine responses to influenza, SeV, and VSV.^{44,117} Uridine and ribose, the defining signatures of RNA, are both necessary and sufficient for TLR7 stimulation.⁴⁵ Furthermore, viral fusion and/or uncoating and endosomal acidification are required for TLR7-dependent recognition.¹¹⁷ Viral RNA, synthetic poly U RNA, and even nonviral, cellular RNA in the endosome is sufficient to stimulate TLR7-dependent cytokine production,^{44,68} indicating that any RNA localized to the endosome is able to trigger TLR7 activation. While influenza virus is recognized upon endocytosis by TLR7, other viruses such as VSV and SeV require replication in the cytosol prior to recognition by TLR7. The latter type of viruses are recognized by TLR7 in the endosome upon delivery of cytosolic viral replication intermediates through the process of autophagy¹⁰⁶ (see below).

TLR9

TLR9 is expressed in pDCs and B cells in humans. Mice express TLR9 in pDCs, B cells, macrophages, and conventional DCs. TLR9 is located in the endosome and mediates recognition of viral DNA. Originally, bacterial DNA sequences containing hypomethylated CpG motifs were shown to activate TLR9.⁶⁹ More recent studies showed that TLR9 might recognize the sugar-base-backbone, 2-deoxyribose, of phosphodiester DNA irrespective of the CpG content.⁶¹ TLR9 is the principal means by which HSV-1 and HSV-2 stimulate type I IFNs in pDCs *in vivo*.^{100,116} Interestingly, a TLR9 molecule “retargeted” to the plasma membrane, unable to respond to viral nucleic acids, however now responded to self DNA that did not stimulate wild-type TLR9.¹⁵ These results suggest that not only is endosomal localization important to trigger TLR-viral nucleic acid interactions, but that endosomal TLRs may limit access to nonviral nucleic acids via an active sequestering mechanism in the endosome.

C-Type Lectins

In addition to TLRs, C-type lectin receptors (CLRs) expressed on the plasma membrane can bind to certain viruses. Classical CLRs contain carbohydrate recognition domain responsible for the Ca²⁺-dependent binding to their ligands. However,

carbohydrate-recognition domains of many CLRs do not bind to Ca²⁺.⁸ CLRs can be classified into those that are used solely for endocytosis of pathogens and those that are used for inducing signaling. The endocytic CLRs include mannose receptor DEC205 and Langerin, which are expressed on CD8 α^+ DCs and Langerhans cells, respectively. Langerin on Langerhans cells are capable of clearing HIV by receptor-mediated endocytosis and degradation in Birbeck granules.³⁷

The signaling CLRs include Dectin-1 and DC-SIGN.⁴⁰ Dectin-1, which is a receptor for fungal β -glucans, contains an ITAM motif in the cytosolic domain, and engages Syk tyrosine kinase and CARD9, leading to NF- κ B activation.⁹⁵ Dectin-1 plays an important role in antifungal defense, but it is not known to have antiviral functions. DC-SIGN binds to HIV-1 and Ebola virus. Signaling through DC-SIGN alone does not lead to the activation of NF- κ B or expression of cytokines, but can modulate signaling through other PRRs. DC-SIGN engagement by viruses leads to serine/threonine kinase Raf-1 activation. After translocation of NF- κ B by TLR-stimulation, DC-SIGN-activated Raf-1 mediates the phosphorylation of NF- κ B subunit p65, which in turn leads to p65-acetylation. Acetylation of p65 both prolongs and increases IL-10 transcription, resulting in increased IL-10 production. However, the majority of C-type lectin-virus interactions reflect a viral invasion mechanism. A clear example of this is DC-SIGN signaling by HIV-1. This interaction results in impaired DC maturation, enhanced T-cell proliferation and transmission of HIV-1 to T cells, thereby promoting systemic infection of the host. DC-SIGN and a related C-type lectin, DC-SIGNR, also enhance infection by Ebola virus.¹³ Another example is Dengue virus, which binds to CLEC5A and induces signaling through DAP12 to induce proinflammatory cytokines. This leads to lethality, not protection, in mice.²⁹

Other Strategies of Viral Recognition

In addition to PRR-based viral recognition, non-PRR-based, cell-autonomous virus sensing mechanisms exist in mammalian hosts. While molecular mechanisms for such pathways are not yet understood, these pathways likely involve sensing various forms of cellular stresses inflicted by virus infection. One of the hallmarks of virus infection is the production of large amounts of viral proteins. This often leads to ER overload, leading to ER stress and unfolded protein response (UPR) induction. Virus infection also often leads to the generation of reactive oxygen species (ROS) by interfering with proper mitochondrial function. In addition, as discussed below, most viruses express molecules that inhibit vital cellular functions such as transcription, translation and secretion. These types of stress that accompany virus infections might be seen by the mammalian host as a signature of virus infection. In conjunction with pattern recognition, such stress sensing pathways can engage signals leading to type I IFNs synthesis, cell-cycle arrest or cell death to avoid further viral replication and spread.

INNATE ANTIVIRAL CYTOKINES

Type I Interferons

Antiviral mechanisms in vertebrates are highly dependent on the action of type I IFNs. Type I IFNs are a family of cytokines that act early in the innate immune response and are key

cytokines capable of inducing an antiviral state in infected and uninfected neighboring cells.⁸⁰ In addition to this antiviral activity, the interferon cytokines have a role in regulating the ensuing adaptive immune response.¹⁷¹ While type II and type III IFNs also have antiviral activities, in this chapter we will focus on the role of type I IFNs in innate antiviral defense. In humans, the type I IFNs consist of 13 α -genes coding for 12 IFN- α subtypes, one β -gene encoding a single IFN- β subtype and a single gene encoding IFN- ω . Type I IFNs bind to IFN- $\alpha\beta$ R, which is a heterodimer of IFN- α R1 and IFN- α R2 chains. High levels of IFN- α subtypes are rapidly secreted from pDCs upon viral recognition, whereas IFN- β can be induced from most virus-infected cell types.

Type I IFN Induction

As described in detail above, stimulation of various PRRs including TLRs (TLR3, 4, 7, 8, and 9), RLRs (RIG-I, MDA-5), and cytosolic DNA sensor(s) leads to the production of type I IFNs. Most virally infected cells trigger the cell intrinsic pathway of type I IFN production through activation of RLRs or DNA sensors. In contrast, pDCs recognize viral genomes within the endosome via TLR7 or TLR9 and induce robust secretion of IFN- α and IFN- β . pDCs are thought to express high constitutive levels of IRF7 and are the only cells capable of coupling TLRs to IRF7 directly, thereby leading to rapid and robust transcription of type I IFN genes.

Amplification of IFN Production by IRF7

In the cytosol of most cells, IRF3 is constitutively expressed while very low levels of IRF7 are found.⁷¹ While IFN- α genes contain ISREs, the IFN- β gene also contains binding sites for NF- κ B and activator protein 1 (AP1). IRF3 is a potent activator of the IFN- β and IFN- $\alpha 4$ gene but not the IFN- α genes, whereas IRF7 efficiently activates both IFN- α and IFN- β genes. Thus, upon activation of RLRs or TLR3, IFN- β and IFN- $\alpha 4$ production is immediately triggered by the IRF3 homodimer binding to the promoter regions of these genes, while the production of other members of IFN- α occurs at a later time point upon IFN- $\alpha\beta$ R-induced production of IRF7. In addition, IFN- $\alpha\beta$ R signaling increases PRR expression (TLRs and RLRs), leading to further amplification of antiviral signaling pathways.

IFN- $\alpha\beta$ R Signaling

The IFN- $\alpha\beta$ R utilizes the so-called JAK-STAT signaling pathway, which is used by many other cytokine receptors. This pathway consists of a receptor, JAK family tyrosine kinases (JAK1, JAK2, JAK3, and Tyk2), and transcription factors (STAT1–6). The receptor complex typically consists of two or three distinct polypeptides that contain in their cytoplasmic domain binding sites for different combinations of JAK and STAT proteins. Upon receptor engagement by its ligand, the receptor complex is assembled, resulting in activation of JAK kinases with subsequent tyrosine phosphorylation of STAT proteins, leading to their dimerization, nuclear translocation, and activation of target genes (Fig. 8.6).

Thus, upon engagement of Type I IFN receptor complex IFN- α R1 and IFN- α R2 by IFN- α , IFN- β or IFN- ω , these receptor subunits dimerize, resulting in phosphorylation of Tyk2, which is associated with the IFN- α R1, by Janus kinase (JAK) 2. Activated Tyk2 subsequently phosphorylates JAK1, which is

FIGURE 8.6. Type I and type II IFN receptor signaling. Type I and type II IFN receptors consist of IFNAR1 + IFNAR2, and IFNgR1 + IFNgR2, respectively. Engagement of the receptors by cognate cytokines induces activation of prebound kinases (Tyk2 and JAK), leading to phosphorylation of STAT proteins. Phosphorylated STAT molecules form dimers, which translocate into the nucleus to initiate transcription of genes. STAT1/STAT2 dimers recruit IRF9, forming ISGF3, which binds to ISRE sequence found in the promoter of many ISGs. STAT1 homodimer binds to the GAS sequence on different sets of ISGs and induces their transcription.

coupled to the IFN- α R2 chain. Signal transducer and activator of transcription (STAT) 1 and 2 are prebound to the IFN- α R2 chain. Activated JAK1 binds to STAT2 and phosphorylates it, creating a binding site for STAT1, causing their dimerization and transport to the nucleus. The STAT1–2 heterodimer forms a transcription complex, ISGF3, with IRF9 to facilitate transcription of ISGs by binding to the sequence motif called interferon stimulated response element (ISRE). In addition, STAT1 homodimers bind to the IFN- γ -activated site (GAS) sequence motif and induce a different set of ISGs (Fig. 8.6).

Inflammatory Cytokines

In addition to type I IFNs, many inflammatory cytokines play an important role in antiviral defense, by directly inducing antiviral effector molecules or indirectly by stimulating cellular recruitment, phagocytosis of infected cells, and activating adaptive immune responses such as cytotoxic T lymphocytes and neutralizing antibodies. Cytokines can act locally through autocrine and paracrine mechanisms or, if produced at high enough levels, they can gain access to the circulation and

induce systemic effects, such as acute-phase response or fever. The major inflammatory cytokines IL-6, IL-1 β , and TNF are produced by virally infected DCs and macrophages, and act systemically with a wide spectrum of biological activities that help to coordinate the body's response to infections. These cytokines are responsible for causing fever by inducing prostaglandin E2, which acts on the hypothalamus, causing increased heat production from brown fat and by inducing vasoconstriction to prevent heat loss through the skin. Fever is thought to be generally beneficial to host defense, because some pathogens may replicate less efficiently at high temperatures. However, the role of fever in host defense is still incompletely understood. IL-6, IL-1 β , and TNF also stimulate the acute-phase response in the liver. Acute-phase proteins secreted by hepatocytes can have direct antiviral effects, for example, by promoting their killing by complement or phagocytes. Finally, IL-6, IL-1 β , and TNF induce leukocytosis, leading to an increase in circulating neutrophils, which are phagocytes that help to clear virally infected cells.

Interleukin 6

IL-6R belongs to the hemopoietin family of receptors, which are tyrosine kinase-associated receptors that form dimers upon binding their cytokine ligand. IL-6R consists of IL-6R α and gp130 chains. IL-6 bound to the IL-6R α chain causes the association of the complex with gp130, resulting in the activation of Jak1, Jak2 and Tyk2, followed by the phosphorylation of Stat3. Phospho-Stat3 dimerizes and translocates into the nucleus, where it activates transcription of target genes. IL-6 is a pleiotropic cytokine with a wide range of biological activities in immune regulation, hematopoiesis, inflammation, and oncogenesis.⁹⁶ IL-6 is induced by a variety of signals including TLR, NLR, and RLR signaling, and is a key cytokine that triggers the acute-phase response, as well as activation of T cells and antibody-producing plasma cells.

Interleukin 1- β and Interleukin-18

As described above, secretion of IL-1 β and IL-18 requires the activation of inflammasomes. Both IL-1R and IL-18R are heterodimers of a ligand-binding α chain and a coreceptor accessory protein (AcP). Both chains contain a TIR domain in the cytoplasmic tail. As such, these receptors recruit MyD88 and induce NF- κ B signaling (Fig. 8.7). IL-1 β through binding to IL-1R induces the expression of hundreds of genes, including cytokines (IL-6 and TNF- α), chemokines (e.g., IL-8), and adhesion molecules that are important for leukocyte trafficking.⁴⁶ In adaptive antiviral immunity, IL-1 β plays an important role in the antigen-driven expansion and differentiation of CD4 T cells.¹⁶ While IL-1R is widely expressed by many cell types, IL-1 β is mainly produced by the sentinel cells of the innate immune system, including macrophages and DCs, although fibroblasts and keratinocytes can also synthesize this cytokine in response to tissue injury or stress signals.^{46,168} On the other hand, IL-18, which is expressed mainly by macrophages and DCs, work alone or in combination with IL-15 prime NK cells for the production of IFN- γ and enhance their cytolytic activity.^{55,76,178} IL-18 in combination with IL-12 or IL-2 alone can also induce differentiation of either Th1 or Th2 cell types depending on the cytokine milieu.^{75,136} IL-18 is also required for optimal cytokine production by CTLs, including IFN- γ , TNF- α , and IL-2.⁴¹

FIGURE 8.7. IL-1R and IL-18R signaling. IL-1R consists of the IL-1R α and IL-1RAcP chains, while IL-18R consists of the IL-18R α and IL-18R β chains. Each chain contains a TIR domain in the cytoplasmic region and, upon receptor engagement by IL-1 or IL-18, recruits MyD88 and induces signaling, resulting in NF- κ B and MAPK activation.

IL-1 β plays an integral role in antiviral immunity against influenza A virus infection. IL-1R^{-/-} mice infected with influenza virus have impaired leukocyte recruitment to the lung, diminished CD4 and CD8 T cell responses, impaired immunoglobulin responses, and succumb to virus-induced fatality.^{78,158} On the other hand, mice deficient in IL-18 were found to have a transient increase in viral titer due to defective NK cytotoxicity after influenza A virus infection but otherwise had normal adaptive immunity to influenza infection.¹¹⁰

Tumor Necrosis Factor (TNF)

TNFR belongs to a group of receptors known as TNFR family, characterized by a cysteine-rich common extracellular binding domain. Upon engagement of the ligand TNF, TNFR forms a trimer (Fig. 8.8). TNFR1 contains a cytoplasmic death domain, which recruits the adaptor TRADD through its death domain. TRADD can assemble two different signaling complexes, involving FADD pro-caspase 8 or RIP1 and TRAF2. RIP1 activates IKK, resulting in the activation of NF- κ B, while TRAF2 stimulates the JNK signaling pathway. Similar to IL-1 and IL-6, TNF is involved in induction of a stereotypic inflammatory response that promotes host defense from a broad range of pathogens, including viruses. Recent studies revealed an additional pathway activated by TNFR—the induction of cell necrosis via the protein kinase RIP3. This TNF-induced necrosis was shown to be important for immune defense against vaccinia virus and CMV.^{31,187}

FIGURE 8.8. TNFR signaling leads to three distinct cell fates. TNF binding trimerizes the TNFR. Through the cytoplasmic death domain, TNFR recruits TRADD, which also contains a DD. TRADD can assemble different signaling complexes. TRADD can recruit FADD through DD–DD interaction, which results in caspase-8 activation, leading to apoptosis. In cells in which caspase-8 is rendered nonfunctional, RIP-3 is recruited to the complex to induce necrosis. In addition, TRADD can also recruit RIP-1 and TRAF2, resulting in signal transduction and activation of NF- κ B and MAP kinase pathways.

Interleukin 15

IL-15 is produced by DCs and macrophages upon viral infection. IL-15R is a trimer of the IL-15R α chain, which is specific to IL-15, and β , and the common γ chains that are shared with IL-2 and other cytokines. An unusual feature of IL-15R complex is that the IL-15R α chain is expressed on the cells that produce IL-15, rather than on the target cell that responds to IL-15. IL-15 forms a complex with the IL-15R α chain in the ER and the two proteins are transported to the cell surface, where they remain associated and function as a ligand for the IL-15R β and the common γ chains expressed on target cells. IL-15R induces activation of STAT5, resulting in expression of anti-apoptotic and growth-promoting genes in target cells.¹²⁰ The main target-cell types of IL-15 are cytotoxic lymphocytes: IL-15 is an important growth and survival factor for CD8 T cells, NK cells, and a subset of NKT cells. Importantly, IL-15 can function downstream of type I IFNs in antiviral immune responses.¹³³

Interferon γ

IFN- γ is secreted mainly by three lymphocyte types, NK cells (during early phase of viral infection), CD8 T cells, and Th1 cells (after induction of adaptive immunity). IFN- γ R, like IFN- α β R, belongs to the type II cytokine receptor family (Fig. 8.6). IFN- γ R is expressed by most cells, and consists of two subunits: IFN- γ R1, the ligand-binding chain, and IFN- γ R2, the signal-transducing chain. As the ligand-binding IFN- γ R1 chains interact with IFN- γ , they dimerize and become associated with two signal-transducing IFN- γ R2 chains. Receptor assembly leads to activation of the JAK1 and JAK2 and

phosphorylation of a tyrosine residue on the intracellular domain of IFN- γ R1. This leads to the recruitment and phosphorylation of STAT1, which forms homodimers and translocates to the nucleus to bind to GAS elements, activating a wide range of IFN- γ -responsive genes. IFN- γ has a potent antiviral function, by inducing transcription of genes encoding antiviral effectors such as PKR and viperin. Note that some antiviral effectors are induced only by type I IFNs and not by IFN- γ , including 2'5'OAS, Mx1, Mx2, and RNaseL.⁴² Instead, IFN- γ R signaling induces activation of genes involved in antigen processing and presentation, facilitating the activation of virus-specific T cells.

CELL-AUTONOMOUS ANTIVIRAL DEFENSE MECHANISMS

Type I IFN-Dependent Antiviral Defense

IFN- α β R signaling leads to the expression of over 300 ISGs. Although the functions of majority of these genes are currently unknown, they are all thought to participate in antiviral defense. The effect of IFN- α β R signaling is different in infected and non-infected cells. In infected cells IFN- α β signals in an autocrine fashion to induce ISGs involved in cell autonomous antiviral defenses. These ISG encode proteins that interfere with multiple steps of viral infection cycles. In specialized noninfected cells, such as APCs and cytotoxic lymphocytes, IFN- α β promotes antigen processing and presentation, along with cytotoxic activity of NK cells and CD8 T cells. In addition, IFN- α β signals in a paracrine fashion to induce an antiviral state in neighboring

cells, thereby minimizing the spread of viral infection. Only a handful of ISGs that have direct antiviral effects have been characterized in detail. Their functions are described below.

2'-5' Oligoadenylate Synthetase (OAS) and Ribonuclease L (RNase L)

OAS and RNase L act in concert to degrade viral RNA in the cytosol. While basal levels of OAS and RNase L are found constitutively, stimulation through IFN- α β R dramatically increases their expression levels. Activated by dsRNA, (2'-5') OAS converts ATP into 2'-5' oligoadenylate, which functions as a second messenger to activate latent ribonuclease RNase L. Activated RNase L degrades viral and cellular ssRNAs, inhibiting protein synthesis and viral growth (Fig. 8.9). Mice deficient in RNase L suffer from increased susceptibility to RNA viruses including Picornaviridae, Reoviridae, Togaviridae, Paramyxoviridae, Orthomyxoviridae, Flaviviridae, and Retroviridae families.¹⁶⁷ However, the roles of OAS and RNase L pathway in defense against DNA viruses remain less clear. Interestingly, the cleavage products of RNase L can serve as ligands for RIG-I and MDA5, leading to amplification of the RLR pathway.¹²¹

Protein Kinase R (PKR)

PKR is a serine/threonine kinase that phosphorylates the α -subunit of eukaryotic translation initiation factor 2 α (eIF2 α). PKR becomes activated through homodimerization upon binding to viral dsRNA structures via its dsRNA binding domains. This results in inhibition of translation and a decrease in total cellular and viral protein synthesis, effectively reducing viral production. In addition to its translational regulatory function, PKR has a role in signal transduction and transcriptional control through the I κ B/NF- κ B pathway.¹⁰² PKR can also mediate apoptosis, cell-growth arrest, and autophagy, all of which curb viral replication and spread in the host.¹⁵¹ In addition to the virus-restricting function of PKR, recent studies indicate that PKR functions to stabilize IFN- α and IFN- β mRNA, thereby ensuring robust IFN protein production.¹⁶⁰ Mice genetically deficient in PKR are susceptible to infection with viruses including rhabdovirus, orthomyxovirus, and orthobunyavirus.

Orthomyxovirus Resistance Gene (Mx) Proteins

Mx proteins belong to a family of GTPases consisting of MxA and MxB in humans and Mx1 and Mx2 in mice.⁶⁵ The Mx

FIGURE 8.9. Type I IFN-induced antiviral mechanisms. Type I IFNs induce over 300 genes, many of which are antiviral effectors. When an IFN-stimulated cell encounters a virus, viral dsRNA activates OAS and PKR. OAS produces 2'5' oligoadenylate from ATP, which activates a latent ribonuclease RNaseL. RNaseL can cleave viral mRNA (as well as host mRNA). PKR activated by dsRNA inhibits translation, thereby impairing viral protein synthesis. Mx gene products trap viral RNP in the cytosol and prevent its nuclear import. ISG15 modifies newly synthesized proteins (most of these are viral proteins) by forming a complex with HERC5. Viperin impairs viral budding by disrupting lipid rafts. Tetherin inhibits viral particle release.

proteins have a large N-terminal GTPase domain, a central interacting domain (CID) and a C-terminal leucine zipper (LZ) domain. Both the CID and LZ domains are required to recognize target viral structures. Viruses targeted by Mx proteins include orthomyxoviruses, paramyxoviruses, rhabdoviruses, togaviruses, and bunyaviruses. Remarkably, transgenic expression of human MxA in IFN- $\alpha\beta$ R-deficient mice confers full resistance to otherwise fatal infection with Thogoto virus, influenza virus, VSV, LaCrosse virus or, Semliki Forest virus,^{67,142} indicating that this effector molecule is sufficient for protective innate defense against these viruses. The main viral targets seems to be the viral nucleocapsid-like structures.⁹⁷ Mx proteins are thought to survey exocytic events and mediate vesicle trafficking to trap essential viral components. It is interesting to note that most inbred strains of mice harbor defective Mx1 gene.⁶³ Therefore, studies using inbred mice must be interpreted with the caveat that they are Mx-1 deficient.

ISG15

ISG15 is an ubiquitin-like molecule that can be covalently attached to target proteins using E1-, E2-, and E3-like enzymes. UBE1L (E1-like ubiquitin-activating enzyme) was shown to be the specific ISG15-activating enzyme.¹⁴⁷ Two E2 ubiquitin-conjugating enzymes, UBCH6 and UBCH8, serve as ISG15 carriers. Subsequently, two E3 ubiquitin ligases—HERC5 (homologous to the E6-associated protein C terminus (HECT) domain and RCC1-like domain containing protein 5) and TRIM25—conjugate ISG15 to protein substrates. All enzymes identified in the ISGylation pathway are coordinately induced by type I IFNs. There are over 150 targets of ISGylation: RIG-I

and STAT1, as well as several IFN-induced antiviral effector proteins. Interestingly, by physically associating with polyribosomes, HERC5 ensures that ISG15 conjugation is restricted to the newly synthesized pool of proteins, which in infected cells will consist primarily of newly translated viral proteins.⁴⁹ Further, ISGylation of a small percentage of human papillomavirus (HPV) L1 capsid protein has a dominant inhibitory effect on the infectivity of HPV16 pseudoviruses. Given that acute viral replication in general requires a vast amount of *de novo* protein synthesis, ISG15 modification of newly synthesized viral protein might be a powerful virus restriction mechanism that can be broadly applicable to many viruses.

Tetherin and Viperin

Tetherin (also known as BST-2, PDCA-1, and CD317) is a GPI-anchored protein that is highly expressed upon type I IFN stimulation. Tetherin associates with lipid rafts and inhibits retrovirus particle release in the absence of Vpu.¹³² Vpu utilizes the beta-TrCP E3 ubiquitin ligase complex to induce endosomal trafficking events that remove tetherin from the cell surface, rendering it incapable of restricting the release of enveloped viruses.¹²⁸ Thus far, tetherin has been implicated in restricting the release of members of the retrovirus, filovirus, and arenavirus families. Viperin (*virus inhibitory protein, endoplasmic reticulum-associated, interferon inducible*) is another IFN-inducible protein that is known to prevent replication of a variety of viruses including HCMV, influenza virus, hepatitis C virus (HCV), dengue virus, alphaviruses, and HIV-1.⁵⁴ Viperin impairs the release of influenza virus by disrupting lipid rafts via suppression of the activity of farnesyl diphosphate synthase,

FIGURE 8.10. Innate restriction of retroviruses. TRIM5 α perturbs the controlled uncoating of the subviral particle prior to reverse transcription. APOBEC3G deaminates cytosine residues in nascent retroviral cDNA, causing C/G to T/A hypermutation and degradation of viral cDNA. Tetherin inhibits retroviral particle release. In contrast, TREX1, an exonuclease, inhibits innate immune detection of HIV DNA by degrading nonproductive RT products.

a key enzyme in isoprenoid biosynthesis¹⁹¹ (Fig. 8.9). In addition, viperin localizes to the lipid droplets⁵⁴ and through a yet undefined pathway interferes with replication of other viruses that do not require lipid rafts for synthesis.

Retroviral Restriction Factors

In addition to the IFN-inducible antiviral molecules described above, cells are equipped with “host restriction” factors that are constitutively expressed in some cell types and are induced by IFNs in others.¹⁸ The host restriction factors that specifically counter retrovirus infections are described below.

TRIM5 α

Members of the tripartite motif (TRIM) protein family are involved in various cellular processes, including cell proliferation, differentiation, development, oncogenesis, and apoptosis.¹³⁴ There are 66 known members of TRIM proteins in humans, characterized by the presence of RING, B-box, and coiled-coil domains. Many of the TRIM proteins display antiviral properties, particularly against retrovirus entry and release.¹⁸⁴ TRIM5 α has been extensively studied as a key factor responsible for antiretroviral activities. TRIM5 α is thought to perturb the controlled uncoating of the subviral particle prior to reverse transcription by recognizing and degrading the capsid protein of retroviruses, resulting in a block of viral replication (Fig. 8.10). Interestingly, TRIM5 α from Old World monkeys confers potent resistance to HIV-1, but not SIV, while the human ortholog of TRIM5 α is unable to specifically target HIV. Strikingly, the differential ability of human and monkey TRIM5 α to restrict HIV hinges on a single amino acid, R332 (human) vs. P332 (monkey).¹⁰⁹ It is likely that HIV and SIV have evolved in their natural hosts to evade interaction with TRIM5 α .

APOBEC Family

APOBEC (apolipoprotein BmRNA-editing catalytic polypeptide) proteins are a group of cytidine deaminases. Members of the APOBEC family contain either one or two catalytic deaminase domains. APOBEC is constitutively expressed in various cell types but its expression can be enhanced by type I and type II IFNs. APOBEC3G becomes encapsidated into retroviral virions in infected cells. Upon viral fusion and entry into the new host cell, APOBEC3G deaminates cytosine residues in nascent retroviral cDNA⁶⁵ (Fig. 8.10). The resulting uracil residues function as a template for the incorporation of adenine, which, in turn, can result in strand-specific C/G to T/A transition mutations that affect virus viability. The antiviral activity of APOBEC3G is strongly inhibited by HIV-1 Vif protein, allowing the virus to replicate virtually unimpaired in APOBEC3G-expressing host cells. Vif induces the ubiquitin-dependent degradation of some of the APOBEC proteins. However, Vif is also able to prevent encapsidation of APOBEC3G and APOBEC3F through degradation-independent mechanisms.

Type I IFN-Independent Antiviral Defense

Type I IFN-dependent antiviral mechanisms are only known to exist in vertebrates. Other animals rely on more ancient forms of antiviral defenses, including RNA interference and autophagy.

RNA Interference

RNAi was first identified as a potent antiviral defense mechanism in plants, then subsequently in fungi, nematodes, and insects.¹⁰⁸ The mechanism of RNAi involves two steps (Fig. 8.11). First, viral dsRNA is recognized by members of the Dicer endonucle-

FIGURE 8.11. RNA interference is an ancient antiviral defense mechanism. In plants and invertebrates, the RNAi pathway plays a major role in the recognition and destruction of viral RNA. Viral dsRNA is recognized by Dicer, which processes such RNA into short RNAi (~20 bp). The processed RNAi is incorporated into the RISC complex, which serves as the guide strand. The guide strand base pairs with a complementary sequence of a viral RNA molecule and induces its cleavage by AGO, the catalytic component of the RISC complex.

ase family, which processes it into siRNA. Second, these siRNA are incorporated into RNA-induced silencing complex (RISC), which guides the RNase enzyme AGO to complementary sequences in viral RNA for cleavage and degradation. In plants and nematodes, but not in insects, this antiviral response is further amplified through a secondary wave of siRNAs generated by RNA-dependent RNA polymerases (RdRPs), which greatly increases the pool of siRNAs available to RISC. To combat antiviral RNAi responses, many plant and invertebrate viruses have evolved to encode proteins that act as suppressors of RNA silencing. Interestingly, in addition to generating RNAi, Dicer-2 was shown to trigger a signaling pathway, resulting in the expression of antiviral genes in *Drosophila*. The latter function requires the helicase domain of Dicer-2, and given its phylogenetic relation to RIG-I, suggests a parallel role of Dicer-2 to mammalian RIG-I in the induction of antiviral genes.³⁸ In mammalian cells, RNAi has not been found in virally infected cells. Further, mammalian cells lack the RdRPs to amplify the siRNA and fail to mount a systemic antiviral RNAi response. Therefore, with the evolution of the potent type I IFN system, the RNAi mechanism may have become obsolete for antiviral defense in mammals.

FIGURE 8.12. Autophagy as innate antiviral defense mechanism. From insects to humans, xenophagy is used to limit viral replication in the cytosol. A double membrane structure called a phagophore forms around the invading or replicating virus, engulfing either the virion or replication intermediate into autophagosomes. Contents are degraded when autophagosomes fuse with lysosomes.

Xenophagy

Autophagy is an ancient, highly conserved pathway responsible for the lysosomal degradation of cytosolic constituents and organelles that is critical in maintaining cellular homeostasis. Recent studies have illustrated an important interplay between autophagy and the innate immune system. Signaling through PRRs can lead to the induction of autophagy. Clearance of intracellular pathogens via autophagy followed by degradation in the lysosome is referred to as “xenophagy” and presents an important mechanism of antiviral defense.¹⁰⁷ Upon xenophagocytosis, virions or viral replication products in the cytosol are engulfed into autophagosomes and degraded in the lysosome for clearance (Fig. 8.12). This pathway of viral clearance was shown to be important in protection of *Drosophila* from VSV infection.¹⁶³ Intracranial HSV-1 infection of mice defective in autophagy results in uncontrolled virus replication and neuropathogenesis.¹³⁷ In addition to xenophagic removal of virions within the cytosol, autophagic clearance of viral proteins or other viral products plays a key role in protection of infected cells, particularly terminally differentiated cell types such as neurons.¹³⁸ Given that multiple human viruses—including HSV-1, HCMV, HIV-1, and gamma herpesviruses—have evolved evasion mechanisms to escape destruction by xenophagy,⁴³ this pathway likely plays an important role in viral sequestration and clearance of viruses in humans.

CELL TYPES INVOLVED IN INNATE ANTIVIRAL RESPONSES

NK Cells

NK cells are cytotoxic lymphocytes that play an important role in antiviral immunity. NK cells detect and eliminate virally infected cells and produce IFN- γ to induce other antiviral mechanisms. The importance of NK cells and antiviral immunity, particularly against Herpesviridae, is highlighted by the fact that an individual identified to have isolated NK

deficiency with no other identifiable deficiency suffered from disseminated, life-threatening varicella infection, followed by cytomegalovirus (CMV) pneumonitis and cutaneous HSV infection.¹⁹ A similar observation was reported for a 2 year old who died of recurrent severe varicella infections.⁵⁰

NK cells express two classes of receptors, known as activating and inhibitory receptors. These receptors induce or inhibit the target cell lysis and IFN- γ production upon recognition of their cognate ligands on target cells (Fig. 8.13). The ligands for activating NK receptors are induced in virally infected cells. The ligands for NK inhibitory receptors are MHC class I molecules and other molecules constitutively expressed on most cells and downregulated upon viral infection. The ligands for inhibitory receptors can be downregulated either as a result of sensing the viral infection in the cell or, in the case of MHC-I, as a result of viral downregulation of MHC-I. Many DNA viruses encode molecules dedicated for evasion of MHC I processing and presentation of viral antigens in order to avoid recognition by CD8 T cells.⁶⁴ Through their ability to detect missing self (reduction in MHC class I molecules on the cell surface), NK cells fulfill the gap in immunosurveillance by CD8 T cells. Thus NK cell recognition of infected cells relies on both the sensing of “induced self” (by activating receptors) and the “missing self” (by inhibitory receptors)¹⁴⁶ (Fig. 8.13). The net effect of these changes is detected by NK cells. Only when positive signals dominate, NK cells induce apoptotic death of target cells by unleashing their cytotoxic granules.

NK receptors fall into two structurally distinct families. One group belongs to the killer inhibitory receptor (KIR) family of proteins, which contains immunoglobulin-like domains. Another group of receptors is known as killer lectin-like receptors (KLRs), and contains C-type lectin domains.¹⁹⁷ Both groups of receptors contain activating and inhibitory receptors. The signaling property is defined by the sequence motifs found in cytoplasmic tails of the receptors or their signaling adaptors. Activating receptors typically contain a short (few

FIGURE 8.13. Natural killer cell activation and inhibition. NK cell recognition of infected cells relies on both the sensing of “induced self” (by activating receptors) and the “missing self” (by inhibitory receptors). NK cells contain cytosolic lytic granules that mediate apoptosis in target cells. **(A)** When an NK cell recognizes a healthy cell, NK cell lysis of the target cell is prevented by engagement of the inhibitory receptor by an normal level of MHC class I on the target cell. **(B)** When an NK cell interacts with virally infected cells that have reduced MHC class I on the cell surface (“missing self”), NK cells induce apoptosis in the target cell. **(C)** When an NK cell recognizes stressed virally infected cell expressing high levels of stimulating ligands (“induced self”), negative signals from inhibitory receptor is overridden by the activating signal, leading to lysis of target cells.

amino acids) cytoplasmic tail and are associated with signaling adaptors via ionic interactions of charged residues within their transmembrane regions. Several adaptor proteins are known to associate with activating receptors: DAP12 (DNAX-activating protein of 12 kDa), which contains the so-called immunoreceptor tyrosine-based activation motif (ITAM), which is a phosphotyrosine signaling module that recruits and activates Syk-72 tyrosine kinase upon recognition of the ligand by the ectodomain of the receptor complex. Another adaptor protein, called DAP10, has a distinct sequence motif that engages the PI3K signaling pathway. This adaptor is used exclusively by the NKG2D receptor, which is discussed in more detail below. In contrast to activating receptors, the inhibitory receptors contain the ITIM motif in their cytoplasmic regions.¹¹⁴ ITIM motifs recruit either tyrosine phosphatase SH2-domain-containing protein tyrosine phosphatase 1 (SHP1) or lipid phosphatase SH2-domain-containing inositol polyphosphate 5' phosphatase (SHIP1), which counter the effects of activating receptors. The opposing effects of ITAM and ITIM motifs

explain how the balance of activating and inhibitory receptor ligands determines the outcome of NK cell recognition.

Both humans and mice express the NKG2 family of KLRs, which heterodimerizes with CD94 and interact with nonpolymorphic MHC molecules such as HLA-E (human) and Qa-1 (mouse). In humans, the NKG2 family consists of NKG2A, B, C, D, E, and F, of which NKG2A and B are inhibitory and C and D are activating. In mice, the Ly49 family of KLR proteins is inhibitory except for Ly49H.

NK-activating receptors include the immunoglobulin domain containing proteins Nkp30, Nkp44, and Nkp46, along with the KLR, NKG2D. The Nkp proteins associate with CD3 ζ homodimers or the Fc receptor γ chain to induce activating signals. NKG2D is unique among the NKG2 family members in that it recognizes non-MHC ligands and associates with DAP10 and DAP12 signaling molecules, and provides activating signals to NK cells.

The ligands for activating receptors are generally absent or expressed at a low level on normal uninfected cells. Their

expression is upregulated in response to viral infection and cellular stress. The best characterized activating ligands are recognized by NKG2D.¹⁰⁴ Human ligands for NKG2D include MHC class-I-chain-related protein A (MICA) and MICB, which are nonclassical MHC I molecules. In mice, NKG2D binds to several ligands including retinoic acid early transcript 1 (Rae1), a glycosylphosphatidylinositol (GPI) anchored protein, histocompatibility 60 (H60), and mouse UL16-binding protein-like transcript 1 (Mult1). While Rae1, H60, and Mult1 only share 20% amino acid sequence homology, they share a structurally related domain that is distantly related to the MHC I $\alpha 1$ and $\alpha 2$ domains. Inducible expression of these ligands can overcome inhibitory signals provided by recognition of normally expressed MHC class I molecules, resulting in target cell lysis (Fig. 8.13C).

NK inhibitory receptors sense the level of MHC class I molecules on target cells. The CD94:NKG2A heterodimers recognize nonpolymorphic MHC class I molecules HLA-E in humans and Qa-1 in mice, which present leader peptides from classical MHC class-I proteins. Thus, when the MHC-I level decreases as a result of viral manipulation, it is reflected in the decreased level of HLA-E/Qa-1 expression, resulting in disengagement of the CD94:NKG2A inhibitory receptor. Not surprisingly, several viruses mimic the activity of HLA-E. UL40 of HCMV confers protection in infected cells by encoding the same leader sequence that can be presented on HLA-E,¹⁸² while HIV-1 selectively avoids downregulation of HLA-E and HLA-C to prevent NK-mediated lysis.³³ The mouse Ly49 family of inhibitory receptors recognizes the polymorphic MHC class I molecules. There are 18 Ly49 proteins in mice that have specificity to different MHC class I haplotypes. This mechanism of NK inhibition has been co-opted by MCMV, which encode m157, which stimulates Ly49I to inhibit NK activation.⁷

Plasmacytoid DCs

Among the leukocytes, pDCs are considered professional viral sensors for several reasons.¹¹¹ First, pDCs are equipped with special cellular machinery to endocytose many types of viruses and transport them to the endolysosomal compartment, whereupon uncoating of viral envelope and capsid, viral genomic DNA or RNA can be detected through TLR9 or TLR7, respectively. Second, pDCs constitutively express molecules involved in signaling to induce type I IFN genes. For instance, these cells express constitutively high levels of IRF7⁹⁴ and utilize IRAK1,¹⁸⁵ TRAF3,^{62,135} IKK α ,⁷⁴ osteopontin,¹⁶⁴ and PDC TREM¹⁹² to induce IRF7-dependent IFN transcription. Third, pDCs form specialized lysosome-related organelles from which TLR9 and TLR7 can engage IRF7 activation to trigger transcription of type I IFN genes. The formation of IFN-inducing organelles depends on the presence of adaptor protein 3 (AP-3).¹⁵⁴

Consequently, pDCs were originally known as IFN-producing cells (IPC), characterized by its potent ability to secrete type I IFNs in response to viruses.^{9,23,59,85} The phenotype of these type I IFN-producing pDCs has been found to differ by species, as they are CD4⁺CD11c⁺BDCA-2⁺CD123⁺ in humans¹⁶⁶ and CD11c^{int}CD11b⁺Gr-1⁺B220⁺SiglecH⁺ in mice.^{9,131} Whereas DCs as a class are thought to be the professional antigen presenting cells specializing in antigen uptake, processing, and presentation to T cells, the predominant role of the pDCs appears to be the secretion of type I IFNs. In particular, pDCs can be induced to secrete large amounts of IFN α when stimulated with viruses including SeV,⁸⁵ influenza,⁹ and HSV-1.^{23,59} However, this

situation may not be universal, as inflammatory monocytes after vaccinia virus infection,¹² and alveolar macrophages after respiratory NDV infection,¹⁰¹ but not pDCs, are the predominant IFN producers, highlighting a differential cell requirement for type I IFN responses dependent on the type of viral stimulus. The pDCs express both L-selectin and CCR7 and enter through the blood vessel into secondary lymphoid tissues.²⁷ At steady state, these cells are not found in peripheral tissues, where they can come in contact with local viral infections. However, they can be induced to migrate into peripheral tissues and secrete antiviral IFNs *in situ*.¹¹⁸ In mice that are depleted of pDCs, reduced early IFN-I production and augmented viral burden was observed after MCMV infection. During VSV infection, pDC depletion enhanced early viral replication and impaired the survival and accumulation of virus-specific cytotoxic T lymphocytes.¹⁷² Thus, pDCs mediate early antiviral IFN-I responses and influence CD8 T cell responses. Given the location of pDCs, these cells likely serve as the initial source for type I IFNs in response to systemic viral infections, and as a secondary source of type I IFNs in response to localized viral infections restricted to the peripheral tissues.

Monocytes

Monocytes are a population of circulating leukocytes that patrol the blood stream and peripheral tissue for infection. Once inside the tissue, monocytes can give rise to macrophages and dendritic cells. Circulating monocytes can be broadly categorized into two types: inflammatory monocytes and patrolling monocytes.¹⁰ Inflammatory monocytes (Ly6C⁺CCR2⁺ in mice and CD14⁺ in humans) are selectively recruited to inflamed tissues and lymph nodes *in vivo*, and produce high levels of TNF- α and IL-1 during infection or tissue damage. Mouse inflammatory monocytes express TLR2 and recognize dsDNA viruses such as vaccinia virus and MCMV, and secrete large amounts of type I IFNs.¹² Interestingly, monocyte recognition of viruses by TLR2 requires endocytosis while recognition of bacterial TLR2 ligands does not. While the exact viral ligands for TLR2-dependent detection by monocytes is unclear, TLR2 is known to be triggered by a variety of viruses including human cytomegalovirus,³⁴ mouse cytomegalovirus (MCMV),¹⁷³ herpes simplex virus types 1 and 2,^{103,156} hepatitis C virus,²⁸ lymphocytic choriomeningitis virus,²⁰³ measles virus,¹⁷ and vaccinia virus.²⁰⁴

The other subset of monocytes (Ly6C⁻ in mice and CD14^{dim} in humans) patrols the blood vasculature, can differentiate into macrophages after extravasation into tissues, and has been suggested to be associated with tissue repair.¹⁰ The human CD14^{dim} monocytes do not express cell surface TLRs but express endosomal TLR7 and TLR8, and after recognition of viral nucleic acids, produce TNF, IL-1 β , and chemokine (C-C motif) ligand 3 (CCL3), but not type I IFNs.³⁵

Macrophages

Macrophages are versatile cells that play central roles in inflammation, wound healing, tissue homeostasis, and tissue remodeling. Macrophages are professional phagocytes, clearing dying cells and pathogens. Macrophage can be found in most organs as specialized cell types, such as Kupffer cells (liver), microglia (neural tissue), and osteoclasts (bone). Macrophages are well known in their defense against bacterial and protozoan pathogens, as they are the chief phagocytes that engulf and degrade these types of pathogens upon activation with IFN- γ . Recent studies highlight the importance of macrophages in

antiviral defense. Macrophages are situated at the forefront of mucosal barriers. In the lung, alveolar macrophages sample and degrade incoming pathogens. In addition, alveolar macrophages become highly infected with respiratory viruses such as Newcastle disease virus (NDV), and produce the highest levels of type I IFNs locally that prevent other cells from becoming infected.¹⁰¹ Not only do macrophages provide the initial type I IFNs in infected tissue, they also serve as “viral sink” to prevent more vulnerable cell types from becoming infected. Subcutaneous injection of VSV results in selective and productive infection of subcapsular sinus macrophages in the draining lymph nodes. These macrophages secrete high levels of type I IFNs that prevent infection of neurons. In mice depleted of such macrophages, local injection of VSV results in infection of innervating neurons in the lymph node and neuropathogenesis and death of mice.⁷⁷ It is interesting to speculate how virus replication niche is supported by the subcapsular macrophages in the face of large amounts of type I IFNs secreted by these cells. Perhaps these subcapsular macrophages have a unique mechanism of resisting viral and IFN-induced cell death.

Dendritic Cells

Dendritic cells are professional antigen-presenting cells capable of stimulating naïve antigen-specific lymphocytes in secondary lymphoid organs. Dendritic cells play an important role in immune responses at multiple levels. First, they are situated at various sites of pathogen entry, and are among the first cells to recognize the incoming pathogens through a set of PRRs. Engagement of PRRs upon viral recognition induces the expression of genes required to both eliminate the pathogens (innate effectors) and to initiate adaptive immune responses.¹²⁶ Second, DCs are the only cell type capable of initiating adaptive immune responses by activating naïve T lymphocytes. Pathogen recognition through PRRs activates DCs to increase their expression of the chemokine receptor, CCR7, which enables them to migrate from the site of infection to the secondary lymphoid tissues, where naïve lymphocytes recirculate (Fig. 8.14). On transit, DCs undergo a maturation program that results in the upregulation of costimulatory molecules and translocation of their MHC class II to the cell surface.¹⁸³ Once in the lymph node, DCs can present antigens derived from the pathogens to naïve T cells and induce their activation (through costimulation) and differentiation (through secretion of appropriate cytokines)¹¹ (Fig. 8.15). A naïve T cell requires three kinds of signals for activation and differentiation. First, a T cell must recognize viral peptides presented by the MHC molecules (signal 1). CD4 T cells bind to peptides presented by MHC class II, while CD8 T cells bind to peptides presented by MHC class I. Second, T cells must receive signals from costimulatory molecules on APCs. PRR stimulation of APCs results in the expression of costimulatory molecules including CD80 and CD86, which bind to CD28 on naïve T cells and provide this second signal that allows optimal clonal expansion. The third signal dictates the differentiation of a naïve T cell into different effector types. CD4 T cells can differentiate into Th1, Th2, and Th17 cells depending on the cytokines provided by the APCs or other accessory cell types. Antiviral responses are mediated by Th1 cells, as they are uniquely capable of secreting IFN- γ .

DCs can be broadly divided into two types, those that reside in the peripheral tissues (mucosa, skin, internal organs; tissue DCs) and those that reside in the blood and lymphoid

FIGURE 8.14. Dendritic cell populations in the peripheral tissues and in the secondary lymphoid organs.

At the mucosal surfaces and in skin, distinct DC populations are found. In intestinal mucosa, CX₃CR1⁺ mononuclear phagocytes extend their dendrites and survey the environment just beneath the epithelial layer, while CD103⁺CD11b⁺ DCs in the lamina propria can take up antigens and migrate to the mediastinal lymph node to prime T cells. In the epithelial layer of the mucosa of the vagina and eye or in the skin, Langerhans cells are the only DCs present in this layer. In the submucosal or dermis, submucosal/dermal DCs survey the environment for pathogen invasion. Both Langerhans cells and submucosal/dermal DCs are able to migrate to the draining lymph node. In most cases, the latter DC populations are required for T-cell priming. Within the lymph nodes, four different DC subsets appear to perform distinct functions. CD8 α^+ DCs are specialized in cross presentation of viral antigens to CD8 T cells, while CD11b⁺ and DN cells are capable of priming CD4 T cells. Plasmacytoid DCs do not participate in induction of effector T cell responses but serve as a key producer of type I IFNs.

tissues (blood DCs).⁸⁴ The blood DCs differentiate from precursors that enter these tissues from peripheral blood. In the mouse lymph nodes and spleen, the blood DCs can be divided into CD8 α^+ DC (CD8 α^+ CD11b⁻), CD4⁺ DC (CD4⁺CD11b⁺), DN DC (CD4⁻CD8⁻), and plasmacytoid DCs (pDCs).^{66,165} In cutaneous lymph nodes or lymph nodes draining vaginal or eye mucosae, two extra DC subsets exist that are derived from the tissue, the Langerhans cells (LCs) and dermal or submucosal DCs^{6,70,150} (Fig. 8.13). In the intestinal lamina propria, a distinct set of tissue DCs surveys the environment.¹⁸⁸ Just beneath

FIGURE 8.15. Innate instruction of adaptive immunity. Within the lymph node, DCs presenting viral antigenic peptides on MHC class I and MHC class II are able to interact with naïve CD8 T and CD4 T cells whose T cell receptors (TCR) are specific to the peptide presented by MHC molecules. PRR engagement (shown here for an endosomal TLR) by viral PAMPs induce expression of costimulatory molecules CD80 and CD86, as well as cytokines that stimulate naïve T cells, providing second and third signals needed for robust T-cell activation and differentiation. T cells receiving all three signals can proliferate and differentiate to become effector T cells. Depending on the cytokines secreted by DCs, CD4 T cells can become various effector Th types including Th1, Th2, or Th17.

the villous epithelial layer, CX₃CR1⁺ mononuclear phagocytes extend their dendrites into the lumen. These cells do not migrate to the lymph node, but play an important role in intestinal homeostasis. In the lamina propria, CD103⁺ CD11b⁺ DCs pick up ingested antigens, and migrate to the mesenteric lymph node to prime immune responses. DC subsets are equipped with specialized cellular machinery to perform distinct functions. For instance, among the blood DC groups, CD8⁺ DCs are equipped with machinery to carry out cross-priming to activate naïve CD8 T cells, while CD8⁻ DCs express proteins involved in the MHC class II presentation pathway leading to the activation of naïve CD4 T cells.⁴⁸ However, migratory DCs from the infected tissues are required to elicit immune responses to localized infections, indicating that both tissue-resident and lymphoid-resident DCs cooperate to prime a robust immune response to pathogens.¹⁰⁵ In contrast, pDCs are specialized in recognizing viruses and secreting high levels of type I IFNs, but are not involved in activation of naïve T cells. Different DC subsets orchestrate innate and adaptive immune responses to viruses, depending on the type of PRR engaged by a given virus infection.

VIRUS MANIPULATION OF INNATE IMMUNITY

Virus–TLR Interaction as Viral Pathogenesis Mechanism

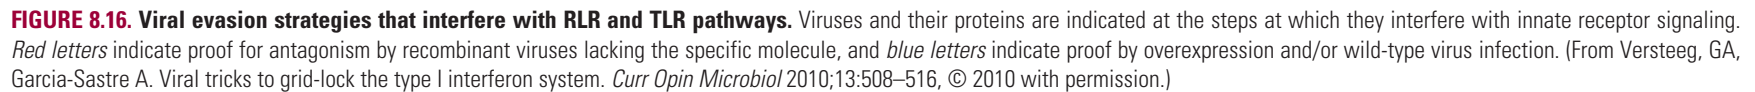

A virus–host PRR interaction reflects either host recognition of viruses to elicit appropriate antiviral defense, or viral strategy to infect the host. As discussed in the previous section, an example of the former is TLR9 recognition of viral DNA within the endosomes. This interaction leads to the activation of type I IFNs and prevention of viral replication in neighboring cells.

However, most TLR–virus interactions that occur at the cell surface belong to the latter category, with the exception of TLR2-mediated recognition of viruses by monocytes (see Cell Types Involved in Innate Antiviral Responses). In fact, certain viruses rely on TLR signaling as a survival mechanism.^{17,89} MMTV persists indefinitely in WT mice, but is rapidly cleared in mice deficient in TLR4 by cytotoxic T-cell response.⁸⁹ MMTV stimulates IL-10 production by B cells through dendritic cell and macrophage activation mediated by TLR4 signaling. IL-10, which is an immune suppressive cytokine, protects the MMTV-infected B cells from removal by cytotoxic T cells. It has been suggested that IL-10 may serve as a master regulator of chronic vs. acute viral infections,²⁰ thus it warrants analyzing whether TLR-dependent IL-10 production plays an important role in the pathogenesis of other chronic viral systems, such as HIV and HCV. Another example in which TLR–virus interaction benefits the virus is the measles virus. The HA protein of measles virus induces cytokine secretion in a TLR2-dependent manner. Interestingly, this interaction also results in upregulated expression of the MV receptor, CD150, suggesting that HA–TLR2 interactions in fact benefit the virus at the expense of the host.¹⁷

Viral Evasion of the Innate Immune System

Virtually all viruses encode factors to counteract the induction, signaling, or antiviral effector functions induced by the type I IFNs.¹⁹⁰ While viruses employ distinct molecules to achieve blockade of the antiviral effects of type I IFNs, these can be categorized into four major strategies: (1) global inhibition of cellular gene expression, (2) evasion from innate recognition, (3) inhibition of molecules involved in the IFN induction and signaling (Fig. 8.16), and (4) inactivation of the IFN-induced effector molecules (Fig. 8.17). A common strategy

Toll-like receptors

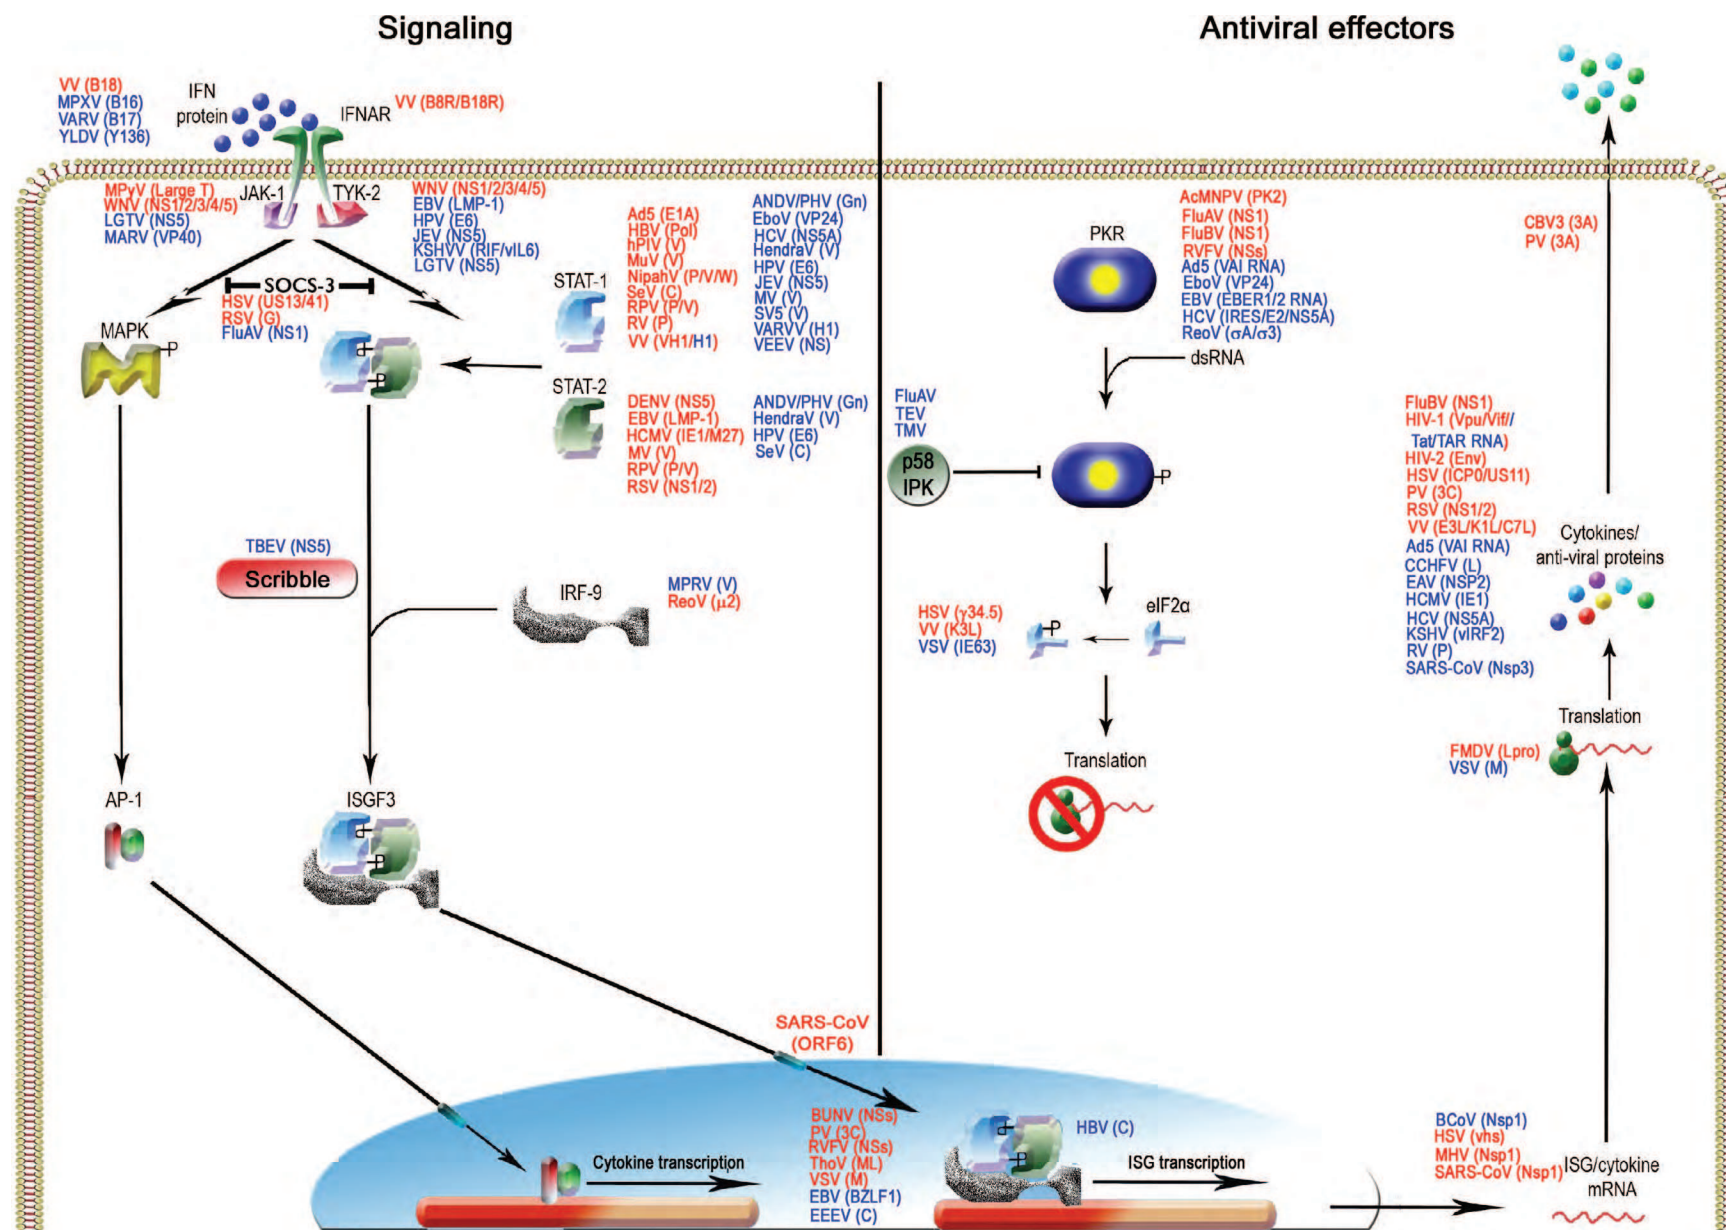

FIGURE 8.17. Viral evasion strategies that interfere with IFN signaling and antiviral effectors. Viruses and their antagonistic proteins are indicated at the steps of the IFN pathway. *Red letters* indicate proof for IFN antagonism by recombinant viruses lacking the specific molecule, and *blue letters* indicate proof by overexpression and/or wild-type virus infection. (From Versteeg, GA, Garcia-Sastre A. Viral tricks to grid-lock the type I interferon system. *Curr Opin Microbiol* 2010;13:508–516, © 2010 with permission.)

employed by many viruses is to inhibit cellular gene expression by interfering with host transcription and/or translation. Viruses that replicate in the cytosol that do not require host transcription for replication often employ strategies to block host transcription altogether. Poliovirus 3C protease and the VSV matrix (M) protein inhibit host gene expression by inactivating transcription initiation factor, TFIID.¹¹⁹ The cleavage of translation initiation factor eIF4G in picornavirus-infected cells is a classic example of virus-induced inhibition of host translation. For this group of viruses, the inhibition of cap-dependent translation has no effect on translation of viral mRNAs because they depend on an internal ribosome entry site (IRES) for translation. Other viruses block the earliest steps in innate recognition by interfering with the function of innate sensors such as MDA-5 and RIG-I. Paramyxovirus V protein prevents MDA-5 dimerization,⁵ and influenza A and B viruses express an NS1 protein preventing the activation of RIG-I by binding and inhibiting the actions of the E3 ligase TRIM25.⁵⁷ A common viral strategy to interfere with IFN gene induction is represented by viral inhibitors of IRF3 and IRF7, master transcription factors of type I IFN genes. Examples include KSHV vIRF3, that block host IRF7 activity,⁸⁸ and rotavirus NSP1, that block IRF3 and IRF7.^{14,161}

Finally, even if the infected cells are able to produce type I IFNs, many viruses encode factors that inhibit signaling through the IFN- $\alpha\beta$ R. SARS-CoV ORF6 protein is involved in preventing nuclear translocation of STAT1 by sequestering nuclear import factors on the ER/Golgi membrane.⁵⁶ Even if the infected cells manage to induce and respond to type I IFNs, influenza virus,¹⁴¹ RSV,¹³⁹ HCV,²¹ and HSV¹⁹⁶ induce SOCS-1 and SOCS-3 expression, which negatively regulates the JAK–STAT pathway.

Differences between Evasion Strategy Mechanisms of DNA vs. RNA Viruses

Even though all viruses encode factors that interfere with host antiviral defense mechanisms, different classes of viruses appear to target different stages in antiviral defense. Nearly all viruses with (–)ssRNA genomes interfere with the innate sensors themselves. By contrast, (+)ssRNA and dsDNA viruses target the downstream IRFs as the means to interfere with IFN induction.¹⁹⁰ Another intriguing feature shared among the dsDNA viruses, particularly poxviruses, is that they encode soluble decoy receptors that bind to secreted type I IFNs and prevent IFN- $\alpha\beta$ R signaling. A key advantage of this strategy, compared to the others, is to be able to prevent neighboring cells from becoming resistant to viral infection.

Another striking difference between the host evasion mechanisms employed by different virus groups is that RNA viruses encode often only one or two molecules dedicated to inhibiting host response, usually through interception at the initiation of innate immune responses. Such a viral factor is usually a nonstructural protein that is expressed in infected cells, and has multiple functions in inhibiting the antiviral mechanisms of the host cells. A good example of this is influenza virus NS1. Despite being only 230aa long, NS1 inhibits almost all stages of antiviral pathways: through sequestration of viral RNA from innate recognition, blocking RIG-I function, inhibition of host mRNA processing and export, inhibition of innate effectors PKR and OAS, and IFN- $\alpha\beta$ R signaling.¹⁹⁰

In contrast, many dsDNA viruses, because of their large genome size, can accommodate multiple genes to specifically inhibit pathways that are useful for their own replicative niche. By expressing soluble IFN-binding proteins that compete with the cellular IFN receptor for its ligand, dsDNA viruses allow for infection and spread to cells that would otherwise be prevented from infection. Another feature associated with dsDNA viruses is their ability to establish latency. To this end, almost all herpesviruses encode molecules that specifically block PKR and its downstream target to block cell-mediated arrest of translation. This strategy is particularly important to ensure survival of the latently infected cells. Other dsDNA viruses have as narrow a target as to inhibit one specific NK receptor ligand. MCMV encodes three proteins—m152, m145, and m155—that reduce surface expression of NKG2D ligands, RAE-1,¹¹² MULT-1,⁹⁹ and H60,¹¹³ respectively, in infected cells. Chronicity of virus infection may result from the ability of dsDNA viruses to manipulate the host immune response by interfering with specific effector mechanisms of various host cell types.

CONCLUSION

In the past 10 years, there has been a tremendous progress in characterization of the innate immune recognition of viral pathogens. The role of type-I IFNs, NK cells, TLRs, and RLRs in antiviral defense is now well appreciated and understood in considerable detail. There are some obvious gaps remaining, such as better characterization of intracellular DNA recognition pathways and their role in immunity to DNA viruses. Most IFN-induced antiviral gene products still have to be functionally characterized. These proteins likely interfere with multiple steps in viral infection cycles. This functional redundancy makes the analysis of their contribution to antiviral defense particularly challenging. Other outstanding questions include the elucidation of the mechanisms that control the expression of ligands for activating and inhibitory NK receptors. These ligands may be regulated by cellular stresses associated with viral infection or by signals from cell-intrinsic pattern recognition receptors. Finally, in the next few years we will likely witness continuous progress in understanding the role of noncoding RNAs, such as micro RNAs and piwi-interacting RNAs in antiviral immunity. Ultimately, the greatest challenge lies with the application of the accumulating knowledge to the management, and potentially even eradication, of major viral infections that continue to threaten our well being.

INTRODUCTION

Viruses have been part of human ecology since the human species first evolved on the plains of East Africa. As humans moved out of Africa to populate the continental landmasses,

viruses—already adapted to the human species—were carried along with other microorganisms as part of the human ecological baggage. With the migration of humans around the world, we were exposed to new viruses present in the animal species that humans encountered. Some viruses, such as the herpesviridae family members, Epstein-Barr virus (EBV), and herpes simplex virus (HSV), have co-evolved with humans and have developed complex mechanisms (e.g., latency) to subvert the host defense mechanisms and sustain themselves in the human population. These viruses generally produce mild disease, except where host defenses are absent or weakened (e.g., in immune-deficient or immune-suppressed individuals). Other human viruses (e.g., measles virus) appear to have evolved mechanisms to persist at low levels in some infected individuals and sustain themselves by infecting previously unexposed individuals (typically children) who then go on to develop mild to severe illness and, in turn, serve as reservoirs for further virus propagation. Animal viruses can also *jump* from their host reservoir to infect humans and produce devastating diseases of potentially pandemic proportions. Notable examples of zoonotic viral diseases are the following: (a) the acquired immunodeficiency syndrome (AIDS) pandemic produced by the human immunodeficiency virus (HIV); (b) the outbreak of severe acute respiratory syndrome (SARS) in 2002 produced by the SARS coronavirus; (c) the 2009 H1N1 swine origin influenza A virus pandemic arising from the genetic reassortment in pigs of viruses with donated genes of human, swine, and avian flu origin; and (d) the periodic outbreaks of highly pathogenic avian influenza infection in poultry since 1997 in Asia and most recently in Africa and Europe, which have resulted in sporadic direct infections of humans with mortality rates approaching 50%. Indeed, the recent reconstruction and analysis of the genome of the influenza virus that caused the 1918 *Spanish flu* pandemic suggest that this virus may have been an avian influenza virus that spread directly to humans (without modification of virus in an intermediate host or the acquisition of genetic information from then-circulating human influenza strains).²⁸⁸

Virus infection can result in acute or chronic disease in virtually any organ and tissue of the body. Furthermore, infection with human papillomavirus (HPV), human herpesvirus 8 (HHV-8), and hepatitis B virus (HBV) and hepatitis C virus (HCV) have been directly linked to the development of cervical cancer, Kaposi's sarcoma, and hepatocellular carcinoma, respectively. Given the pandemic outbreak of the swine origin A/California/2009 (H1N1) virus infection, the possibility of another human influenza pandemic from an avian influenza source, as well as the devastating effects of HIV infection all suggest, virus infection represents a continuing threat to human health. We can point to some notable successes in the struggle against viruses (e.g., the eradication of smallpox in the 1970s, and the effectiveness of the live attenuated oral polio vaccine in eliminating paralytic polio in the developing world, raising the prospect of eradicating polio worldwide). Both of these vaccination successes rely on the mobilization of the body's major defense against virus infection—the adaptive immune system. Our enthusiasm about these *successes* must be tempered, however. Because of the success of smallpox eradication, mandatory smallpox vaccination was discontinued in the United States in the early 1970s, making a large fraction of the population (i.e., those younger than age 40) now susceptible to smallpox.

This fact, along with the advances in poxvirus genetics and genetic engineering, now makes smallpox a major bioterrorism threat. Similarly, administration of live oral polio vaccine to children in underdeveloped countries whose immune function is compromised by malnutrition or HIV infection can result in outbreaks of paralytic polio caused by infection with virulent mutants (revertants) of the live attenuated vaccine strain. This realization has prompted a modification of the guidelines for oral polio vaccine administration in the United States and a reevaluation of the prospect of global polio eradication using current vaccination strategies. To counter the continuing threat posed by viruses, it is essential to understand the body's primary defense against virus infection in the immune system.

OVERVIEW OF THE ADAPTIVE IMMUNE RESPONSE TO VIRUS INFECTION

Viruses are obligatory intracellular parasites; that is, they replicate within cells of the infected host and use the cell's biosynthetic machinery for replication and production of progeny virions. Furthermore, most viruses replicate rapidly in infected cells (i.e., within hours) producing progeny virions capable of infecting additional cells, thereby propagating and sustaining infection in the host. These properties of infection by viruses dictate how the immune system must respond to counterinfection. In acute virus infection, the race between the replication of the virus and the host response will result either in the death of the host or in virus clearance and the termination of infection. The tissue injury produced by viruses at the site(s) of infection results both from the cytopathic effects of virus replication and, equally importantly, from the host immune response to infection. In general, therefore, the greater the extent of virus replication in the infected host, the greater the tissue injury and illness severity.

In chronic infection, the time scale of virus replication in the host is not measured in days (as in acute infection) but in weeks, months, or even years, with the host immune response likewise continuing over the same prolonged time scale. Viruses that produce chronic, persistent infection have evolved mechanisms to suppress or alter the immune response (allowing these viruses to persist in the infected host). The tissue injury produced by the immune response to virus infection (termed, *immunopathology*) occurs with both acute and chronic virus infection. In many chronic virus infections (e.g., HCV infection); however, immune-mediated tissue injury predominates (rather than direct virus-mediated injury).³⁸ Furthermore, the clinical manifestations of virus infection (e.g., fever, headache, myalgia, anorexia) are caused primarily by inflammatory mediators (e.g., cytokines) released by cells of the immune system in response to infection. Undoubtedly, chronic (persistent) virus infection also alters or modifies the immune system and its capacity to respond to microbes and environmental antigens.²⁹⁷ Finally, the triggering of the immune system by virus infection can result in the induction of aberrant immune responses directed both to the virus, and to self-cellular constituents, resulting in autoimmune disease.¹⁴³

The primary host defenses against virus infection are physical/chemical barriers to infection and the immune system. The immune system can be divided into two components: the innate immune system (see Chapter 8) and the adaptive immune system. This division is based on the properties of

TABLE 9.1 Cells of the Immune System

Type	Subtype	Onset of effect
Innate immune Cell		
Granulocytic	Neutrophil, basophil, eosinophil	Immediate/inducible (hr)
Monocytic	Macrophage, DCs	Immediate/inducible (hr)
Lymphocytic ^a	NK cell, NK T cell	Immediate/inducible (hr)
Somatic cell (nonhematopoietic)	Epithelial, endothelial cell, etc.	Immediate/inducible (hr)
Adaptive immune Cell		
B Lymphocyte	—	Inducible (d)
T Lymphocyte	CD4 ⁺ , CD8 ⁺ , T _{reg}	Inducible (d)

DC, dendritic cell; NK, natural killer; TCR, T-cell antigen receptor; T_{reg}, regulatory T-cells; hr, hour; d, day.

^aSpecific subtypes of T lymphocytes [e.g., $\gamma\delta$ T cells and intraepithelial (IEL) CD8⁺ $\alpha\alpha$ T lymphocytes] are considered to be part of the innate immune system. These cell types with lymphocytic morphology employ a TCR-type antigen recognition system, but differ in their function and strategy of antigen recognition from conventional T cells.

the immune cell types and molecules involved in the response to infection and the tempo of the response (Table 9.1). The response of the innate immune system to virus infection is either immediate (i.e., constitutively active) or rapidly induced (i.e., typically within hours of infection). The innate immune response is triggered in two ways: first, through recognition of viral constituents (e.g., viral nucleic acids) by a limited set of cellular pattern recognition receptors for foreign molecules displayed on innate immune cells; and, second, through the activation of intracellular signaling mechanisms following virus entry into cells and the initiation of virus replication. Importantly, a defining feature of the innate immune response is that repeat exposure to a particular virus generally evokes an identical response from the innate immune system (although a form of that enhanced efficiency of pathogen recognition has recently been reported for natural killer (NK) cells.²⁹⁸ The genes encoding these receptors and associated signaling mechanisms within innate immune cells are encoded within the germline (i.e., fixed in the genome).

By contrast, the response of the adaptive immune system to a first encounter with a virus takes days to evolve. The response of the cells of the adaptive immune system (i.e., B lymphocytes and T lymphocytes) is triggered by viral constituents, primarily through the engagement of highly specific cell-surface recognition receptors generated by somatic gene rearrangement and displayed by a minuscule fraction of the total repertoire of adaptive immune cells for any given virus. These receptors only recognize the constituents (antigens) of that particular virus. Importantly, this arm of the immune system *adapts* to repeat exposure to a particular virus or viral protein; this results in a more rapid response of higher magnitude by the specific adaptive immune cells on repeat exposure/infection—a phenomenon called *immunological memory*, the basis for vaccination.

The constituents of the innate immune response include proteins of the complement system, and so called *acute phase proteins* (e.g., members of the collectin protein family).²⁵¹ These molecules are present *constitutively* in the blood and tissue fluids or are induced rapidly in the liver following infection and can bind directly to certain viruses, thereby inhibiting virus infection. Leukocytes, in particular, neutrophils, blood monocytes, tissue macrophages, dendritic cells, NK cells and NK T cells are the dominant, innate immune cell types responding to virus infection. They are triggered/activated through

the engagement of pattern recognition receptors (e.g., Toll-like receptors [TLRs], C-type lectins) expressed on their cell surface, which recognize viral constituents (e.g., viral nucleic acids), and in the case of NK and NK T cells, alterations of the cell surface of infected cells. These cells reside in the tissues, and they respond there or are recruited to sites of infection from the bloodstream through the action of cytokines/chemokines released during infection.

Nonhematopoietic body cells (e.g., epithelial cells, endothelial cells, fibroblasts) that are targets of virus infection, must also be considered part of the innate immune response because, on infection, they are triggered to secrete antiviral proinflammatory mediators such as type 1 interferons and certain cytokines/chemokines (the production of which can initiate and amplify the innate immune response to infection). The induction of the innate immune response and the role of innate immune cells and molecules in controlling virus infection are discussed in detail elsewhere (Chapter 8). One of these innate immune cell types, the dendritic cell (DC), however, bridges the innate and adaptive immune response, and its role in the initiation of the adaptive immune response is discussed in a later section of this chapter.

A hallmark of the adaptive immune response is the exquisite specificity of adaptive immune cells for a particular foreign viral antigen, and the capacity of this system to recognize and respond to a myriad of viruses (or other antigens). This remarkable property of the adaptive immune cells is achieved by the generation of a correspondingly diverse array of cell surface recognition receptors, which are randomly generated within the lymphocytes of every individual and clonally distributed among the adaptive immune cells. As a consequence, in a nonimmune individual, only an extremely small fraction of the adaptive immune cell repertoire (e.g., one cell in a million or less) will have an antigen receptor capable of recognizing a specific virus (viral antigen). Understanding how this diverse array of clonally distributed antigen receptors is generated during lymphocyte development and how that rare adaptive immune cell directed to particular virus finds virus or infected cells in a peripheral site of infection (e.g., the skin or lungs) is critical to the understanding of the adaptive immune response to virus infection.

Viruses, because they exist as extracellular virion particles and replicate/assemble within infected cells, pose a unique recognition problem for the adaptive immune system (i.e., how

TABLE 9.2 Properties of T and B Lymphocytes

General properties	B lymphocytes	T lymphocytes
Origin	Bone marrow	Bone marrow
Self/non-self-discrimination	Bone marrow	Thymus
Activation	BCR and other ligand receptors	TCR and other ligand receptors
Antigen recognition	Native (3D) conformation	Nonnative fragments
Antigen receptor	B lymphocytes	T lymphocytes
Somatically generated	+	+
High specificity	+	+
Clonally represented	+	+
Localization	Cell surface/secreted (Ab)	Cell surface only

BCR, B-cell antigen receptor; TCR, T-cell antigen receptor; 3D, three-dimensional; Ab, antibody.

to recognize the virus [viral proteins or genome] both outside of the cell and within the infected cell). The elegant solution to this problem employed by the adaptive immune system is the partitioning of the adaptive immune system into two distinct cell types: B and T lymphocytes (Table 9.2). B lymphocytes displaying a receptor specific for a particular virus will, on encounter with the virus and activation, release their antigen receptor in a soluble form (i.e., as antibody molecules) capable of binding free (extracellular) virions in a highly specific matter. This interaction typically results in virus neutralization and/or elimination. Antiviral B-lymphocyte responses are exquisitely sensitive to the three-dimensional confirmation of the virus (and its constituents), and they play a dominant role in clearing virus during infection, in preventing or limiting reinfection (after previous virus infection), and in vaccination against a specific virus.

Activated antiviral T lymphocytes retain their antigen-specific receptors on the cell surface and are responsible for recognizing and eliminating virus-infected cells. T lymphocytes, however, do not recognize viral proteins in their native conformation. Rather, the antigen receptors on the T lymphocytes recognize *processed* peptide fragments of viral proteins displayed on the infected cell surface bound to cell-surface molecular recognition platforms (i.e., the major histocompatibility complex [MHC] locus gene products). Activated virus-specific T lymphocytes halt the spread of infection by killing virus-infected cells through direct cell-to-cell contact and by the release of soluble mediators (e.g., cytokines, such as IFN- γ and tumor necrosis factor α [TNF- α]). By releasing these and other soluble mediators, the activated T lymphocytes recruit and orchestrate the response of the innate immune cells which, in turn, act to clear infection. Understanding how and where B and T lymphocytes activate, the mechanism of antigen presentation to the cells, and the range of effector activities that these cells use to control and eliminate virus is essential for understanding the adaptive immune response to virus infection. These important topics are reviewed in this chapter.

Finally, the importance of the immune system in general and the adaptive immune response in particular in controlling virus clearance and promoting recovery from infection is exemplified by the fact that viruses have evolved a variety of mechanisms to inhibit or alter the host immune response. Whereas the virus immune evasion strategies are best considered in the context of viral pathogenesis (Chapter 10) and are addressed in chapters dealing with individual viruses, this chapter high-

lights some of the viral evasion strategies directed to the adaptive immune response.

ARCHITECTURE OF THE ADAPTIVE IMMUNE SYSTEM

Generation of T and B Lymphocytes: Primary Lymphoid Organ

Unlike the cells of the innate immune system, T and B lymphocytes possess one unique and profoundly important property. On their surfaces, these cells also display a receptor complex capable of recognizing foreign (nonself) structures—with exquisite specificity. This receptor complex is both randomly generated (by somatic recombination of genetic elements ultimately encoding the mature receptors) and clonally distributed among progeny lymphocytes during their differentiation from progenitor cells. Therefore, of the approximate 10^9 naive T and B lymphocytes in the human adaptive immune system, each cell may, in principle, display a unique receptor directed to a specific foreign antigenic structure. This common property of the antigen receptor on T and B lymphocytes (i.e., random generation by somatic DNA recombination and clonal receptor display) immediately raises two important questions. First, if these antigen receptors are stochastically generated, how is the generation of lymphocytes with receptors to self-structures (e.g., tissue proteins) avoided/prevented? Second, if the frequency of lymphocytes with a receptor directed to a specific foreign antigen (e.g., the coat proteins of an invading virus) is extremely low (1 in 10^7 lymphocytes), how can those rare lymphocytes locate the antigen quickly enough to respond before the infection is beyond control? As is discussed below, it is the unique structure of the primary (central) lymphoid organs where lymphocyte progenitors develop into mature T and B lymphocytes, and of the secondary (peripheral) lymphoid organs where mature T and B lymphocytes respond to invading microorganisms that provides the answers to these questions.

Mature T and B lymphocytes are derived from lymphoid progenitors present in the bone marrow, as well as in sites of hematopoiesis in developing fetus (e.g., the liver) through a process of differentiation and selection linked to, and driven by, the antigen receptors displayed by these cells.^{221,233} As described in Table 9.2, B-lymphocyte lineage development occurs in the bone marrow and follows a well-defined, step-wise program of gene

activation (e.g., expression of the recombination activating gene 1 and 2 [*RAG1* and 2], lymphoid DNA-specific recombinases), and sequential rearrangement of immunoglobulin (Ig) V_H , D_H , J_H , and C_H heavy (H) chain genetic elements (by random somatic recombination), followed by rearrangement of the Ig K/λ V_L - J_L - $C_{LK/\lambda}$ light (L) chain locus elements. Then B-lymphocyte progenitors transit from the pro-B, through the pre-B, and to the surface immunoglobulin-positive immature B-lymphocyte stage. It is during this development/differentiation program that the B-lymphocyte receptor (B-cell receptor [BCR]) diversification occurs through random association of one of the 40 V_H gene segments with one of the 25 D_H and 6 J_H and 70 V_L with 9 J_L to yield (after nucleotide addition and/or excision at the site of gene segment recombination) 10^7 or more different potential BCR H and L chain combinations. During this development process in the bone marrow, T-Lymphocytes expressing a BCR with reactivity to self-molecules (i.e., proteins, lipids, carbohydrates, nucleic acids) will, as a result of BCR engagement, undergo a process of negative selection. These *self-reactive* B cells are largely eliminated/deleted through interaction of the BCR on the developing cells, with self-constituents resulting in apoptosis or in activation ("anergy") of self-reactive B lymphocytes. The immature B lymphocytes that escape negative selection undergo final maturation, migrate from the bone marrow to join the pool of mature B lymphocytes that circulate through the blood, and populate the secondary lymphoid organs. B lymphocytes ultimately express their effector activity by releasing the BCR of the mature B lymphocyte in a secreted form as immunoglobulin (antibody) molecules. This fact has the following two important implications for the recognition of viruses by B lymphocytes: (a) the B-lymphocyte response to viruses will be particularly effective when interacting with free/extracellular virus constituents (e.g., virions); and (b) the BCR and its antibody product will be sensitive to the conformation of viral constituent recognized.

T-Lymphocyte lineage development follows a program similar to that of B lymphocytes. The T-cell antigen receptor (TCR) is also a heterodimer consisting of two polypeptide chains, each of which is formed by somatic recombination of variable (V), diversity (D), and joining (J) segments encoding the variable portion of one chain (or V and J joining for the other chain) to a constant (C) gene segment. As in B lymphocytes, the randomly recombined gene segments encoding the V region gene segment joined to the respective C region gene segment for the two TCR chains encodes the TCR on the developing T lymphocyte. Unlike the BCR, however, the TCR always remains cell associated. Therefore, the TCR is normally directed to foreign antigens (or self-structures) that are cell associated. Consequently, T lymphocytes are uniquely suited to recognize cells that have been invaded by microorganisms (e.g., viruses and intracellular bacteria). Unlike the BCR, the TCR does not recognize intact microbial products, but rather recognizes small fragments of molecules—typically, short peptide fragments of microbial or self-proteins bound to protein products of the mammalian MHC genetic locus (e.g., the classically defined major human transplantation antigens). These MHC gene products expressed on cell surfaces serve as molecular platforms, both selecting and displaying the self-peptides involved in TCR selection during T-lymphocyte precursor development, and presenting microbial peptides to mature T lymphocytes responding to uptake/infection of cells by the microbes. The steps in the processing (fragmenting) and presentation of both self and microbial gene products by the MHC locus protein,

and the structure of the major classes of MHC locus proteins (i.e., MHC class I and II proteins) are discussed below.

The generation of mature T lymphocyte from committed lymphocyte progenitors (arising in the bone marrow) occurs primarily in the thymus (Fig. 9.1). Here, immature thymocytes undergo the developmental program resulting in the formation of mature T lymphocytes, which then leave the thymus, enter the circulation, and ultimately populate secondary lymphoid organs. Two classes of mature T lymphocytes are produced in the thymus. The major population (~80% of the peripheral T lymphocyte pool) are the $\alpha^+\beta^+$ T cells (because their heterodimeric TCR express two chains encoded by TCR α and β loci). The second minor population of mature T cells are the $\gamma^+\delta^+$ T cells (because they express a related two-chain TCR derived from the TCR γ and δ loci). Much of our current information on T-lymphocyte development comes from analysis of $\alpha^+\beta^+$ T-cell development. These T lymphocytes represent the T-cell subset that responds primarily to viral infection, and the selection process of these T cells in the thymus will be emphasized here. The $\gamma^+\delta^+$ T-cell subset likely plays a secondary role in the adaptive response to most virus infections, and the properties/function of this T-cell subset is summarized below.

T-Lymphocyte development in the thymus proceeds in a stepwise fashion with the sequential generation and expression of one (i.e., TCR- β or TCR- δ), and then the other (i.e., TCR- α or TCR- γ) TCR chain by random somatic recombination as thymocytes mature. A complex of four cell-surface molecules called CD3 (CD3 γ , δ , ϵ , and ξ), which are noncovalently associated with the TCR and are critical for signaling through the TCR, are also expressed during T-lymphocyte development. Specific antigen recognition by the TCR- $\alpha:\beta$ (or $\gamma:\delta$) heterodimer is transduced into the cells by the CD3 complex. Concomitant with the expression of the rearranged TCR chains and the signal transducing CD3 complex, the developing thymocytes simultaneously express two co-receptor molecules, CD4 and CD8. Early in the developmental program, thymocytes do not express CD4 or CD8, and they are classified as immature, *double-negative* thymocytes. As thymic development/differentiation proceeds, immature thymocytes that express both CD4 and CD8 co-receptors (as well as CD3 complex and the TCR- α and β chains) and, at this point, are classified as $CD4^+/CD8^+$ *double-positive* thymocytes. CD4 and CD8 molecules recognize structurally conserved domains on the MHC class II and I molecules, respectively. As a result of binding to MHC molecules displaying self-peptides on the surface of thymic stromal cells, CD4 or CD8 also delivers signals to the developing immature thymocytes. The combined signaling by TCR/CD3 complex and the CD4 or CD8 co-receptor directs the development of the immature thymocytes into *single-positive* $CD4^+$ or $CD8^+$ mature thymocytes (expressing TCR, CD3, and either CD4 or CD8).

Because the TCR does not recognize foreign molecules directly (but rather small fragments of molecules bound to MHC molecules), the TCR generated and expressed on developing thymocytes must recognize both MHC molecules and the peptide fragments bound to these molecules. The source of these peptides bound by MHC class I and class II molecules are self-proteins expressed by several different cell types in the thymus. The selection of the thymocytes that ultimately become mature co-receptor *single-positive* T lymphocytes ($CD4^+$ or $CD8^+$) and populate the secondary lymphoid organs is a process in the thymus of positive and negative selection.

FIGURE 9.1. T-Lymphocyte development and selection in the thymus. The progenitors of mature peripheral T lymphocytes arise in the bone marrow as mononuclear stem cell progenitors committed to T-cell lineage development, but lacking cell surface receptors characteristic of T-lymphocyte lineage (e.g., T-cell receptors [TCRs] or the co-receptors CD4 and CD8). These TCR- and co-receptor-deficient “double negative” (DN) cells enter the thymic cortex (a) from the bloodstream as CD4/CD8-deficient DN lymphocytes. In the case of conventional TCRαβ T cells, the DN cells also lack antigen receptor. The cells then undergo a multistep differentiation process (b), which results in cells simultaneously expressing both CD4 and CD8 as well as a low level expression of the TCRαβ receptor complex—so-called double-positive (DP) thymocytes. Within the thymic cortex and medulla (c), the DP cells first undergo “positive selection”—that is, selection for those cells with TCRαβ and CD4 or CD8 co-receptor complexes capable of interaction with self-peptide/major histocompatibility complex (MHC) ligands. DP thymocytes that interact with self-peptide/MHC ligand with insufficient avidity die (undergo apoptosis). The surviving DP thymocytes then transition into either CD4⁺ or CD8⁺ single-positive (SP) thymocytes, which then undergo a process of “negative selection.” In this case, only those SP thymocytes with an appropriate immediate affinity for self-peptide/MHC complexes survive and go on to traffic through the thymus into the bloodstream to ultimately proceed to the secondary lymphoid organs (d) as mature peripheral CD4⁺ or CD8⁺ T cells. The TCRγδ T cells likewise arrive in the thymus (a) as DN progenitors, which eventually upregulate the γδ TCR (b) and undergo a form of positive and negative selection (c) without upregulation of the canonical co-receptors through a selection process that is not well understood. The TCRγδ T cells will exit the thymus (d) and populate peripheral sites including mucosal surfaces and secondary lymphoid organs. Natural regulatory T-cells (T_{reg}) cells (not shown) undergo selection for recognition of self-peptide/MHC class II ligands late in thymocyte differentiation by a selection process poorly understood at this time.

At a specific development stage, immature double-positive thymocytes (expressing the randomly generated α:β TCR, CD3, and both CD4/CD8) encounter, within the thymic cortex, thymic cortical epithelial cells displaying MHC class I and II molecules complexed with self-peptides. Most of these thymocytes (~80%) have randomly generated TCR that are unable to bind to the self-peptide/MHC molecular complexes. In the absence of a signal delivered through the TCR, these thymocytes will die by apoptosis. Those double-positive thymocytes whose TCR can bind the self-peptide/MHC complexes above a threshold avidity augmented by either a CD4 or a CD8 co-receptor binding to the MHC molecule will undergo

positive selection and survive. If the thymocyte TCR can bind peptides bound to MHC class II molecules in association with the CD4 co-receptor, this interaction will result in the silencing of the CD8 co-receptor gene. This signaling event results in the development of a CD4⁺ single-positive thymocyte whose TCR recognizes (is restricted to) peptides bound to MHC class II molecules. Similarly, the double-positive thymocytes whose TCR and associated CD8 molecule can recognize MHC class I/self-peptide complexes with sufficient avidity to survive (i.e., those that are positively-selected) will give rise to MHC class I-restricted CD8⁺ single-positive thymocytes by a similar silencing mechanism of the CD4 gene.

After undergoing positive selection, the surviving single-positive thymocytes are all auto-reactive (i.e., directed to self-peptide/MHC complexes). Therefore, a process of negative selection must then ensue to eliminate/reduce self-reactive, mature peripheral T cells. Although less well understood, negative selection of the $\alpha:\beta$ TCR-expressing single-positive ($CD4^+$ or $CD8^+$) thymocytes probably occurs in both the thymus cortex and medulla. Negative selection is most efficiently mediated by mononuclear cells of hematopoietic origin (e.g., dendritic cells and macrophages) that simultaneously display MHC class I and II molecules expressing self-peptides. The 10% to 20% of thymocytes that survive positive selection, by definition, are auto-reactive. It is likely (but not certain) that the intracellular signal transduction cascade associated with TCR engagement is altered in the cortical and medullary single-positive thymocytes following positive selection. As a result these cortical and medullary thymocytes acquire the TCR-signaling profile of mature T lymphocytes. Consequently, when the thymocytes encounter the self-peptide/MHC complexes displayed by hematopoietic origin cells like DC in the cortex and medulla, those thymocytes whose TCR/ $CD4$ or $CD8$ co-receptor complex recognizes self-peptide/MHC complexes with a sufficient avidity to activate will be eliminated (i.e., undergo negative selection—death by apoptosis). Thymocytes directed to self-“tissue specific” molecules (e.g., insulin) are deleted through

the action of the autoimmune regulator (*AIRE*) gene. This gene is expressed in thymic medullary stromal cells and triggers the transient low level expression of many extrathymic tissue-specific self-proteins in these cells resulting in negative selection of tissue-reactive single-positive thymocytes. Therefore, only about 2% to 5% of immature thymocytes will survive the positive and negative selection processes. These remaining thymocytes will have the properties of mature $CD4^+$ or $CD8^+$ T lymphocytes (i.e., they have TCR that recognize peptide/MHC complexes, but will only interact with the MHC molecules with sufficient avidity to activate when the appropriate foreign [microbial] peptides are bound to the MHC molecule). Following positive and negative selection, these single-positive $\alpha:\beta$ T lymphocytes ($CD4^+$ or $CD8^+$) will leave the thymus to populate the secondary lymphoid organs as peripheral T cells (Fig. 9.1). The $CD4^+$ or $CD8^+$ $\alpha:\beta$ T cells represent 70% to 80% of the circulating extrathymic T-cell population—the primary T-cell population that responds to virus infection.

The second (minor) population of thymus-derived cells that populates peripheral sites is that of the $\gamma:\delta$ T cells, so named because they employ a heterodimeric TCR whose variable (and constant) region is encoded by a distinct set of genetic loci (the γ locus and the δ locus) homologous to the α and β TCR loci¹⁰³ (Table 9.3). These TCR genes rearrange in the thymus in a manner analogous to that of the

TABLE 9.3 T Lymphocyte Subsets

TCR $\alpha:\beta$	Dominant T-cell Type Responding to Virus Infection
$CD8^+$	Recognize major histocompatibility complex (MHC) class I viral peptide complexes, and are important adaptive immune antiviral effector cells
$CD4^+$	Recognize MHC class II viral peptide complexes, and regulate B-cell differentiation and host inflammatory responses to infection
T_H1	Effector $CD4^+$ T cells that produce proinflammatory antiviral cytokines (e.g., IFN- γ) characterized by mononuclear cell inflammatory infiltrates
T_H2	Effector $CD4^+$ T cells that produce cytokines linked to allergic responses (e.g., IL-4, IL-5)
T_H17	Effector $CD4^+$ T cells that produce pro-inflammatory cytokines (e.g., IL-17A/F, IL-6) associated with antibacterial responses and characterized by neutrophil-rich inflammatory infiltrates
T_{FH}	Activated $CD4^+$ T cells that produce cytokines /chemokines (e.g., IL-21), which facilitate B-cell differentiation in SLO and which are retained in the SLO
TCR $\gamma:\delta$	Play a prominent role as “innate-like” effector cells
	–Express the CD3 complex, but usually not CD4 or CD8
	–The generation process of $\gamma:\delta$ TCR chains in the thymus is similar to that of the dominant TCR $\alpha:\beta$ T-cell TCR
	–Present in the circulation and lymphoid organs and prominently expressed at body surfaces (e.g., gut, skin)
	–Recognize products of stressed cells—no restriction in recognition by MHC class I/II molecules, but can recognize lipid complexed to MHC class Ib molecules
NKT	Act as “innate-like” immune effectors early in immune responses
	–Express conventional TCR $\alpha:\beta$ chains, and can use a restricted number of possible TCR genes (i.e., invariant NK T-cells [iNKT cells])
	–Express CD4 molecules (most NK T cells) and NK cell markers, but not CD8 molecules
	–Recognize products of stressed cells and can recognize lipid moieties displayed by MHC class Ib–related molecules on cell surfaces
	–Activation of TCR triggers release of regulatory cytokines (e.g., IL-4)
T_{reg}	Conventional TCR $\alpha:\beta$ T cells that control the response of T and B lymphocytes to foreign (e.g., viral) antigens and self-proteins
	–Dominant population expresses CD4 and CD25
	–May occur spontaneously during T-cell differentiation (natural Treg cells) or after exposure to foreign (e.g., viral) antigen (inducible Treg cells)
	–Regulates (usually suppresses) the response of $CD4^+$ T cells and $CD8^+$ T cells to infectious agents and self-constituents

dominant $\alpha:\beta$ TCR T-cell homolog. The generation of $\gamma:\delta$ T cells in the thymus precedes $\alpha:\beta$ T-cell development. The $\gamma:\delta$ T cells are generated in two waves during T-cell development in the fetus. The first wave of maturing thymocytes consists of cells with limited TCR V gene diversity (i.e., utilize one or few V γ and V δ rearrangement in their TCR). After selection, these $\gamma:\delta$ T cells leave the thymus, traffick through the circulation, and preferentially localize to epithelial surfaces, particularly the skin, gut, and urogenital tract. The second wave of $\gamma:\delta$ T cells, as with $\alpha:\beta$ T cells, displays a highly diverse TCR array, and these cells localize to the secondary lymphoid tissues. Unlike the $\alpha:\beta$ TCR, however, the $\gamma:\delta$ TCR does not recognize peptides bound to the MHC class I or II locus products. Rather, $\gamma:\delta$ T cells either directly recognize structures such as heat shock proteins displayed on the surface of the infected cells, or recognize lipid or glyco/phospholipids moieties bound to MHC-like molecules (e.g., nonpolymorphic MHC Ib molecules) on the surface of stressed (infected) cells. The subset of intraepithelial $\gamma:\delta$ T cells, in particular, differs from the $\alpha:\beta$ T cells, and appears to function like cells of the innate immune system, recognizing not a specific pathogen, but alterations in epithelial cells induced by infection with microbes such as bacteria. At present, no direct role for $\gamma:\delta$ T cells in the control of virus infection has been firmly established although this T-cell subset has been implicated in the control of HIV and herpesvirus infection in humans.⁵

Among the other T-lymphocyte subsets (Table 9.3) generated during development are NK T cells, so-called because these $\alpha:\beta$ TCR-expressing T cells display cell-surface markers shared with NK cells, most notably the C-type lectin NK 1.1. NK T cells are divided into two subsets CD4⁺ CD8⁻ or CD4⁻ CD8⁻ based on co-receptor expression. One subset of NK T cells employs a range of $\alpha:\beta$ V gene combinations in their expressed TCR. The other NK T-cell subset is similar to CD4⁻ and CD8⁻ $\gamma:\delta$ T cells, in that the cells utilize a limited number of TCR $\alpha:\beta$ V genes in receptor generation and are classified as invariant NK T cells (iNK T cells). The iNK T cells recognize foreign and self-lipid/glycolipid bound to MHC-like cell-surface CD1 molecules. The NK T cells with diverse TCR usage by contrast, directly recognize self- or microbial gene products rather than peptide/MHC complexes. Although not as yet certain, the CD1/lipid complexes and the self-moieties (e.g., heat shock proteins) recognized by NK T cells are likely produced or upregulated by cells in response to virus infection.

One T-lymphocyte subset has recently been recognized as a critical regulator of the adaptive immune responses to both infectious agents and self-molecules: the regulator T lymphocyte (T_{reg}) subset. The TCR on T_{reg} cells utilize rearranged $\alpha:\beta$ TCR gene products, and appear (at least in experimental animals) to arise late in thymic development (i.e., after the major wave of both $\gamma:\delta$ and $\alpha:\beta$ T-cell generation). As mature thymocytes, T_{reg} cells appear able to recognize self-peptides bound to MHC molecules and directly activate without undergoing negative selection. Therefore, T_{reg} cells that display primarily the CD4 co-receptor exist both in the thymus (as mature thymocytes) and in the periphery (i.e., in secondary lymphoid organs) as *activated* CD4⁺ T cells. The encounter with self and the resulting activation of T_{reg} cells, however, does not result in autoimmunity. Rather, recent evidence suggests that these T cells suppress/downregulate the activity of conventional CD4⁺

and CD8⁺ T cells responding to viral infection. Although both the role of T_{reg} cells in adaptive immune responses and their mechanism of action are not yet fully understood, these cells may prevent the development of excessive injury during T-cell responses to infection, and suppress the development of autoimmune responses during viral infection. Recent emerging information on the role of T_{reg} cells in virus infection is discussed in a separate section below.

Secondary Lymphoid Organs: Structure and Function

The mature naïve (resting) B and T lymphocytes that egress from their development site (bone marrow and thymus, respectively) enter the blood, and then migrate to secondary (peripheral) lymphoid organs (SLOs). The SLOs play a critical role in the initiation of the adaptive (T- and B-cell) immune response to viruses and other microbes. The major SLOs are the lymph nodes (LNs), the spleen, and the so-called mucosal-associated lymphoid tissue (MALT). LNs are highly organized structures located at vessel convergence points in the lymphatic system, a system that collects fluids and cells from the tissues of most internal organs (e.g., liver, stomach) and body surfaces (e.g., skin, mucosa of the gastrointestinal [GI], genitourinary [GU], and respiratory tracts). The capacity of lymphatic vessels to collect antigen (e.g., virus, viral constituents) from the body surfaces/tissues, and deliver them to the LNs (where antigen concentrates) is essential for the efficient triggering of the adaptive immune response to microbes. The spleen plays a role similar to that of the LN network; however, the spleen is uniquely suited to collect antigen (virus) directly from the bloodstream, because of its unique architecture and extensive blood circulation. The third class of SLOs, the MALT, is composed of specialized lymphoid aggregates associated with major mucosal surfaces and sites of microbial invasions (e.g., the GI, GU, and respiratory tracts). The gut-associated MALT (also called GALT) includes tonsils, adenoids, appendix, and Peyer's patches in the small intestine. In the respiratory tract are similar, but more diffuse, aggregates of lymphoid tissues associated with the epithelium of small/medium airways (i.e., bronchial-associated lymphoid tissue [BALT]). As with the other SLOs, the MALTs are sites of antigen localization where the initiation/induction of the adaptive immune response can occur.

The common feature of SLOs is the localization of adaptive immune cells (i.e., T and B cells) to distinct regions of the SLOs. For example, most B cells are localized in distinct follicles within the LN cortex. Activation of B cells specific for a pathogen/antigen leads to their proliferation and formation of a germinal center within the LN cortex. T cells within the LN localize to, and are diffusely distributed within, the LN paracortical areas. Other cell types are also distributed within the outer cortex and central medulla of the normal LN. These include stromal cells and cells of macrophage and DC lineage. These cells (particularly DC) play a crucial role in the induction of the adaptive immune response, and serve to direct T-cell/B-cell localization to distinct LN regions through the constitutive release of small (low molecular weight) chemotactic proteins—chemokines. A similar segregation of B cells/T cells to distinct regions occurs within the white pulp of the spleen and the MALT (likewise, under control of chemokines elaborated by SLO-resident cells).

Induction of Adaptive Immune Responses in the Secondary Lymphoid Organs

The body's complement of B and T cells consists of more than 10^9 cells, each of which may display a unique antigen receptor directed to a specific epitope. Therefore, the frequency of B or T cells directed to a specific pathogen is extremely low (e.g., a frequency of 1 of 10^4 to 10^6 naïve B or T cells). The problem faced by the adaptive immune systems is that these rare, antigen-specific cells are distributed randomly throughout the body, and must be rapidly mobilized to respond to invading organism. These rare antigen-specific cells must first contact antigen, then activate and generate effector cells capable of eliminating the pathogen. The solution to this problem is achieved through the process of lymphocyte recirculation through the SLO.^{57,273}

Naïve (primary) T cells and most naïve B cells do not permanently reside in the SLOs. Rather, the T and B cells are constantly migrating from the blood through the SLOs and back to the bloodstream. Lymphocyte recirculation is controlled by the expression of distinct homing receptors (adhesion molecules) whose ligands are expressed on cells within the SLO. Naïve $CD4^+$ and $CD8^+$ T cells within the bloodstream express on their surface the adhesion/homing receptor, CD62L (L-selectin). T cells entering the blood vessels encounter the CD62L ligands—the mucin-like moieties CD34 and GlyCam-1 that are constitutively displayed in the endothelium of specialized high endothelial venules (HEVs) within the LN cortex. The interaction of CD62L (on the T cell) with its endothelial cell ligands arrests the T cell's migration through the blood vessel, which results in its binding to the HEV endothelial cell. Other adhesion receptors displayed on endothelial cells that recognize carbohydrate ligands displayed on the surface of lymphocytes (as well as the $\alpha_1\beta_2$ integrin, lymphocyte function-associated antigen 1 [LFA-1] displayed on lymphocytes) also contribute to the arrest of T-cell migration. The naïve circulating T cells also constitutively express a chemokine receptor (CCR7) that recognizes specific chemokines (CCL19, CCL21) displayed on the surface of the HEV endothelial cells. These chemokines are produced by the HEV cells and by cell types within the LN (e.g., DC and stromal cells). The chemokines produced by the latter cell types diffuse into the HEV and are bound to/displayed on, the surface of the HEV endothelial cell. The interaction between the CCR7 receptor on the arrested T cells and its chemokine ligand triggers the migration of the naïve T cells through the HEV and into the LN cortex (parafollicular T-cell region). If the T cells do not encounter antigen, they traffic through the LN cortex to the LN medulla, and then exit the LN through the efferent lymphatic vessels, and ultimately return to the bloodstream where the process of recirculation through the SLO begins again. The egress of naïve T cells from the LN is as noted above, controlled by a chemotactic receptor S1P1R for the lipid sphingosine-1-P (S1P). S1P is present at higher concentrations in lymph and blood than in the LN. S1P1R engagement attracts naïve T cells away from the LN and back into the circulation. Antigen recognition by T cells transiently downregulates S1P1R retaining the antigen detecting T cells in the LN.

Naïve B cells traffic through the LN by similar mechanisms and transiently localize to the lymphoid follicles along a chemokine gradient mediated by a specific chemokine receptor, CXCR5, displayed on the surface of circulating naïve B

cells. Lymphocyte trafficking through the spleen and MALT are likewise regulated by the interplay of adhesion receptor/ligand interactions and chemokines constitutively expressed in these SLOs. In the case of MALT, a set of unique receptor/ligand interactions (restricted to these sites) guides the trafficking of adaptive immune cells to these specialized mucosal sites.

Afferent lymphatic vessels are localized in all body surfaces/tissues, and they drain into the LN. Virus infection of a body surface/tissue triggers the innate immune system—the initial defense against infection. Innate immune cells located at the body surfaces/tissues (specifically, DC and monocyte/macrophages) encounter pathogen, take up virus/viral antigen, and then activate/migrate through the afferent lymphatics to the draining LN. In the draining LN, these migrating cells (along with DC and, to a lesser extent, monocyte/macrophages present in the LN cortex) serve as antigen-bearing presenting cells (APCs) to the naïve B and T lymphocytes trafficking through the LN. As a result of encounter with antigen displayed on the APCs, the lymphocytes with antigen receptors specific for the antigen or pathogen will no longer traffic through the LN, but rather will be retained in the LN (due to S1P1R downregulation) and initiate the process of activation and differentiation, leading to the generation of specific effector B and T cells directed to the pathogen. Therefore, the SLO concentrate antigen in a specific site where the rare antigen-specific, naïve B and T cells circulating through the body can encounter and respond to the pathogen. Afferent lymphatics can also carry large particulates (e.g., viruses as well as “soluble” viral proteins) directly to the LN where the particulates can be captured by macrophages lining subcapsular lymph node sinuses and subsequently delivered to DC or presented to naïve T cells, as well as directed along with soluble antigens through fibroreticular conduits to B cells and a lymphoid follicles.^{95,125}

If infection by a virus is localized to the body surface (e.g., papillomavirus infection of the skin or influenza virus infection of the respiratory tract), then the adaptive immune response to that pathogen will be induced primarily in the LN draining these sites. Virus infections that result in systemic spread (i.e., viremia) will also induce adaptive immune responses in the spleen. Viruses that infect sites where MALT is prominent (e.g., rotavirus infection in the Peyer's patches of the small intestine) will trigger the local induction of the adaptive immune responses at the site of MALT localization.¹⁹⁶

ANTIGEN PRESENTING CELLS AND THE INDUCTION OF ADAPTIVE IMMUNE RESPONSES

As with most microorganisms, viruses enter the body surfaces where the initial encounter with the immune system occurs. These body surfaces (e.g., skin and mucosa of the GI, GU, and respiratory tracts) contain epithelial lining cells, which can serve as the initial cells supporting virus replication. The epithelial surfaces also contain DC, specialized cells of bone marrow origin, which serve as both infection sentinels and APCs, which migrate to the SLOs and deliver antigen to the adaptive immune cells that are trafficking from the blood to the SLOs. A large body of evidence now suggests that DCs are critical APCs for the induction of the primary adaptive immune (T cell) response.¹⁸⁴

For our purposes, two classes or types of DCs, conventional DCs (cDCs) and plasmacytoid DCs (pDCs) can be distinguished. cDCs are localized to the body surfaces and SLOs where they exist as immature (inactive) DCs prior to infection and carry out the aforementioned sentinel and APC function. As discussed below, a subset of cDCs identified by expression of CD8 α in the SLO and α E integrin CD103 in mucosal tissue has the capacity to efficiently take up and present cellular material—for example, apoptotic-infected cells, particulates like viruses, and soluble proteins—to naïve CD8⁺ T cells without direct infection of the DC. pDCs, so-called because of their plasma cell-like morphology are derived from blood monocyte precursors and recruited to sites of inflammation/infection where, following activation, they are major producers of type 1 α -interferons.⁸⁰ In most circumstances these important innate immune effectors cells have limited capacity to act as APC for naïve T cells.

cDCs localize to the epithelium within the epithelial cell layer (e.g., Langerhans' cells in the skin) at the junction of the epithelial basement membrane in GI and respiratory tracts, as well as in the mucosa and submucosa underlying the epithelial surface. The cDCs at body surfaces are derived from circulating monocytic progenitors originating in the bone marrow, which are present in the blood and migrate to the body surfaces and differentiate into peripheral (tissue) DCs. These tissue DCs exist as immature (inactive) DCs at these sites, turn over at a low variable rate, and are replenished by the circulating blood monocyte progenitors that enter the tissues.

Immature DCs are sessile cells that have a particular set of phenotypic markers or characteristics. They express low to intermediate levels of cell-surface MHC class I and class II molecules; the latter (class II) molecules are found predominately not on the DC surface, but within specialized endocytic vesicles. Immature DCs also express low levels of cell-surface molecules, which serve as co-stimulatory ligands for naïve lymphocytes (e.g., CD80, CD86, CD40, CD83).²⁷² These molecules play a critical accessory role in the triggering of naïve antigen-specific (e.g., virus-specific) T cells, ultimately leading to the generation of effector (i.e., antiviral) T and B cells, and the formation of memory T and B cells directed to the pathogen. In addition, immature DCs have the ability to take up particulate and fluid-phase antigen into pinocytic/phagocytic vesicles with high efficiency. The enhanced capacity of these DCs to take up material (including the remains of infected apoptotic cells) likely accounts for their unique capacity to serve as APCs.¹⁸⁵

The initiation of an inflammatory response at the body surface (as produced by virus infection) triggers the DC activation (maturation) process. Activation of the tissue-resident DC results in the *de novo* expression/upregulation of chemokine receptors (notably, CCR7), which renders the activated DCs capable of migrating from the peripheral tissue, primarily through lymphatic vessels along a gradient of constitutively expressed CCR7 ligands, the CCL19/CCL21 chemokines produced by lymphatic endothelial cells. Activation of the tissue DCs is also accompanied by upregulated expression of MHC class I/II molecules, and co-stimulatory ligands resulting in the maturation of the DCs, which, on activation/maturation, characteristically express high cell-surface levels of MHC class I/II molecules and the co-stimulatory ligands, CD80/86, CD40, and CD83. Mature DCs migrate to the SLOs where they act as the principal APCs for the induction of the adaptive

immune response. Therefore, DCs (and to a lesser extent macrophages) serve the dual role of delivery (concentration) of antigen to the SLOs and acting as APCs to retain/activate the rare antigen-specific adaptive immune cell entering the SLOs from the circulation.

Immature DCs can be triggered to activate by virus infection through at least three mechanisms:

1. *Direct infection* of immature DCs. The stimulus for DC activation/maturation is provided primarily by the interaction of viral nucleic acids with (and signaling through) microbial pattern-recognizing Toll-like receptors (TLRs) displayed by DC,¹²⁹ and/or activation of intracellular antiviral signaling mechanisms mediated by the RNA-activated protein kinase (PKR kinase),²⁴⁰ the retinoic-acid-inducible protein I (RIG-I) helicase systems,¹³⁰ and for some viruses the caspase/IL-1 β -associated inflammasome.²⁸⁹
2. *Uptake of virus* and soluble antigen (or more likely the remnant of infected epithelial cells that have undergone apoptosis in response to infection) with activation of immature DC through binding to one or more scavenger or C-type lectin receptor(s), for example, dendritic and epithelial cells, 205 kDa (DEC-205); dendritic cell-specific intercellular adhesion molecule-3 grabbing non-integrin (DC-SIGN) displayed on DC with specificity for carbohydrates on viral glycoproteins/glycolipids²⁷⁴ or through the process of phagocytic uptake.
3. Dendritic cell activation/maturation induced by *inflammatory mediators* (i.e., cytokines, such as TNF- α) released by infected epithelial cells and tissue macrophages in response to TLR and/or intracellular antiviral signaling.

The first two types of virus encounters with immature DC will result in the initiation of the adaptive immune response by delivery of virus/viral antigen to the SLO presented by the activated/mature DC. The significance of inflammatory mediator-induced DC maturation in the induction of the antiviral immune response is still not clear, because the activated, mature DC would not directly deliver viral antigen and would not serve as an APC.

Direct infection of immature DCs and the subsequent migration of the activated/mature DCs to the SLOs would appear to be the most likely mechanism to ensure the induction of an effective antiviral adaptive immune response. Whereas this mechanism of viral antigen delivery to T and B lymphocytes in the SLO occurs,³⁶ it raises the important question: *How do viruses with a very narrow cell tropism, which are unable to either infect or express viral genes in hematopoietic cells like DC (e.g., papillomaviruses) initiate an immune response?*

The capacity of certain immature cDCs to take up and internalize cellular debris such as apoptotic remnants of infected epithelial cells provides the most likely mechanism for triggering adaptive immune T-cell responses. This process of the uptake of infected cell material with presentation to T cells by cDCs is called cross-presentation²⁵⁹ and is carried out by CD8 α ⁺ cDCs in SLO and by CD103⁺ cDCs at mucosal surfaces. Indeed, the speculation based on evidence from experimental viral infection is that endocytic uptake of virions or material from virus-infected cells may be the primary/sole mechanism of viral antigen presentation—at least to virus-specific naïve CD8⁺ T cells.²³⁰ The relative contribution of direct presentation (virus infection of DC), and *cross-presentation* of viral antigen remains controversial²⁹⁶ and will differ for different viruses.

Naïve (primary) T lymphocytes have stringent requirements for activation that include both TCR antigen receptor engagement by the appropriate processed antigenic peptide/MHC complexes and engagement of co-stimulatory receptors (e.g., CD28) displayed on naïve T cells by their corresponding ligands (e.g., CD80/86) along with peptide/MHC complexes by APC. Mature, antigen-bearing DCs are uniquely suited to carry out this process. The inflammatory response triggered by virus infection triggers DC maturation/migration. Virus infection also results in the infection of and/or antigen uptake by tissue macrophages. However, the migration of infected DC and macrophages along with infectious virions (either cell-associated or free) from the body surface to the SLO, not only initiates an immune response in the SLO, but also can in many instances spread infection to other sites in the body. One classic example of this is the dissemination of poxvirus from a peripheral infection site (body surface) to the SLOs, where free (infectious) virions and infected cells carried from the inoculation site to the SLOs can result in additional virus replication there, followed by virus entry into the bloodstream.⁷⁸ Migrant macrophages are probably not as efficient as mature DCs in triggering primary immune response, but they may also serve as a potential APC in the induction of recall memory (secondary) immune responses where the requirements for memory T- and B-lymphocyte activation are less stringent.⁷¹ In this regard, it should also be noted that the mature migrant DCs that have entered the SLOs in response to virus infection may not be the primary APCs for T-cell activation. Several lines of evidence suggest the LN-resident DCs (particularly, CD8 α expressing cDCs) can capture viral antigen delivered by migrant DCs (or macrophages), and present that antigen to naïve (primary) T lymphocytes in the SLOs—not by direct infection, but by the transfer of viral antigen from migrant antigen-bearing DCs to SLO-resident DCs through cross-presentation.²⁹⁶ Intact virions and/or soluble (free, intact) viral antigen, however, undoubtedly contribute to the induction of effective antiviral antibody response by B lymphocytes (as discussed in a later section of this chapter).

Studies examining the induction of adaptive immune responses using confocal and intravital multiphoton microscopy in intact viable LN have provided new insight into the early interaction events between DC-APCs and antigen-specific B and T lymphocytes.^{27,255} Some studies indicate that, on entering the draining LN, activated (mature) DCs migrate under a chemokine gradient stimulus to the paracortical T-cell regions in the vicinity of the HEV.³⁵ Therefore, antigen-bearing DCs would be in the precise location to interact with naïve virus-specific B and T lymphocytes that have entered the draining LN from the circulation and, thereby, initiate the adaptive immune response. However, soluble antigens (viral proteins) and particulates such as virions that entered the LN via lymphatics may be presented to T cells, and particularly B cells, by mechanisms not involving DC migration from the site of infection.⁹⁴

Activation of T and B Lymphocytes in the Secondary Lymphoid Organs

The precise localization of T cells, B cells, DCs, and macrophages within the SLOs is controlled by chemokines, which are largely produced by stromal cells of the SLOs, and by bone marrow-derived cells (e.g., SLO-resident DCs). In draining LN, naïve (primary) T cells that are present in the circulation

will enter the LN through the specialized HEV, where they encounter mature DCs (and macrophages) displaying processed antigen bound to MHC molecules, which are localized to sites in the parafollicular cortex of the LN facilitate interaction with T cells. Most naïve CD8⁺ T cell and CD4⁺ T cells entering the LN will not recognize the antigen (i.e., they have TCRs that fail to recognize the processed antigen with sufficient avidity to activate the cells). These T cells will ignore the DCs and migrate from the LN cortex to the medulla, then enter the efferent lymphatics, and ultimately return to the bloodstream to continue their perpetual search for relevant antigen.²⁷³ A similar process of lymphocyte egress through the HEV occurs in the MALT; for example, Peyer's patches of the small intestine where antigen uptake by mucosal DCs and direct viral antigen transfer to the gut MALT through specialized intestinal epithelial cells, called M cells, result in antigen delivery to these mucosal lymphoid aggregates.¹⁵⁰ Viruses that enter the bloodstream (i.e., produce viremia) as well as any antigen-bearing tissue DCs that, on maturation, bypass the LN and gain access to the circulation will localize to the splenic white pulp. Here, circulating T and B lymphocytes enter the splenic white pulp by transiting through splenic arterioles where viral antigen-bearing DCs can encounter lymphocytes. The lymphocytes that do not recognize antigen will exit the splenic white pulp by entering trabecular veins, and re-enter the circulation.

The rare naïve CD8⁺ T cells and CD4⁺ T cells that recognize processed antigenic peptides displayed on the APC surface in the SLO do so through TCR engagement. The activation of naïve T cells leading to the induction of the adaptive immune response is a multistep process (at both the molecular and cellular level).¹¹² For induction of antigen-specific (virus-specific) CD8⁺ T-cell responses, the activation process requires both interaction of the antigen-specific TCR $\alpha:\beta$ chain complex with *processed* antigen fragments bound to MHC class I molecules on the APC surface, with sufficient avidity and interaction of the CD8 molecule on the T cell with a region of the MHC class I molecule distant from the site of peptide binding. To fully activate the naïve CD8⁺ (or CD4⁺) T cells, additional signaling events must occur, including binding of the co-stimulatory receptor, the CD28 molecule, displayed on naïve T lymphocytes with its ligands, CD80/86, which are displayed at high levels on mature (activated), antigen-bearing DCs. The sequence of events resulting in the activation of antigen-specific naïve CD4⁺ T cells parallels the steps in CD8⁺ T-cell activation, except that the antigen-recognizing TCR $\alpha:\beta$ chain complex must bind (with sufficient avidity) the antigenic peptides bound to MHC class II molecules displayed by APC; and the CD4 co-receptor on CD4⁺ T cells, in turn, must interact with a distinct site (outside of the region of peptide binding) on the MHC class II molecule. One important early consequence of CD4⁺ T-cell activation by antigen is the upregulation of the expression of the CD154 molecule on activated CD4⁺ T cells. CD154 (also called CD40 ligand or CD40L) is a member of the *TNF* gene family, and, as its name implies, is a ligand for CD40 (a TNF receptor gene family member). CD40 is expressed on both activated/mature DCs and antigen-activated B cells. Engagement of CD40 on DCs and B cells by CD154 (CD40L) on activated CD4⁺ T cells has important consequences for the function of these cells. Engagement of CD40 on DCs results in increased synthesis of certain cytokines (notably IL-12) by the antigen-bearing DCs in the SLO, which promotes CD4⁺ and CD8⁺

T-cell differentiation into effectors.¹⁴² For B cells, the interaction between CD40-activated B cells and CD40L expressed on activated CD4⁺ T cells is critical for B-cell differentiation into antibody-secreting effector B cells (plasma cells).¹⁸² Strategies to modulate the CD40/CD40L interaction *in vivo* may have important consequences in vaccine development.

The engagement of the TCR/co-receptor complex, and the CD28 co-stimulatory receptor on T cells in the SLO are the first two critical steps in the induction of a T-cell response to a foreign antigen. This initial antigen encounter by the TCR on specific T cells is called *signal 1* in the lexicon of lymphocyte activation/differentiation. The engagement of the CD28 co-stimulatory receptor is designated as *signal 2*. As a consequence of their interaction with antigen and co-stimulatory ligand displaying DC APC, the naïve T cells halt their transit through the SLO (i.e., downregulation of S1P1R, and are retained there). The APC/T cell encounter leading to signal 1 and 2 transmission in the T cells appears to be of short duration (from 6 to 24 hours), after which the initial programming for T-cell activation/differentiation is independent of additional interaction with antigen.^{174,293} Delivery of signals 1 and 2, although necessary, is not sufficient in itself, however, to ensure full T-cell activation/differentiation and the generation of effector and memory T cells to the antigen. A third signal, signal 3, is required to complete the T-cell activation/differentiation program in the SLO. Signal 3 is delivered by soluble mediators (i.e., cytokines and chemokines) produced primarily by cells of the innate immune system (e.g., pDCs mature/activated in cDCs, NK cells, NK T cells), which enter the SLO in response to infection/antigen deposition in the SLO. IL-12 produced by mature (activated) DC in the SLO is a particularly critical type of signal 2 in T-cell responses to virus, because engagement of the IL-12 receptor on activated CD8⁺ T cell and CD4⁺ T cells promotes their differentiation into effector T cells with potent antiviral activity (e.g., the generation of cytolytic T cells).¹⁹⁹

Other cytokines produced during T-cell activation (e.g., type 1 and type II/III IFNs [IFN- α , β , IFN- γ , IFN- λ , respectively], IL-1, IL-4, IL-6, IL-10 and so on) by innate immune cells responding in the SLOs to virus infection will dramatically modulate the magnitude and type of both the effector and memory T-cell responses. These and other soluble mediators modify the course of T-cell activation/differentiation during the T cell's residence in the SLO.¹⁴²

Similarly, in addition to CD28, other co-stimulatory receptors belonging (like CD28) to the Ig receptor gene family (e.g., Cytolytic T-Lymphocyte antigen-4 [CTLA-4]; inducible T-cell co-stimulator [ICOS]; programmed death-1 [PD-1]) and the TNF receptor gene family (e.g., CD27, OX40, 4-1BB, CD40L) whose expression on activated T cells is temporarily regulated following T-cell activation in the SLO, can either positively (ICOS, CD27) or negatively (PD-1, CTLA-4) regulate the tempo and magnitude of T-cell activation and differentiation into effector cells in the SLO or in peripheral sites of virus infection following interaction with their perspective ligands on APC.^{248,252}

The temporal sequence of signal 1, 2, and 3 delivery to T lymphocytes in the SLO is reflected in the morphologic change of the naïve (primary) T cells from small, resting cells to activated lymphoblasts. This is followed by proliferative expansion of the antigen-specific T-cell *clones* in the SLO, and their differentiation into both effector T cells and an expanded population

of memory CD8⁺ T cell and CD4⁺ T cells. T-cell proliferation is extremely rapid (cell cycle time of ≤ 6 hours and in one report ≤ 2 hours,³¹⁷ with estimates of individual naïve T-cell precursors undergoing 8 to 20 divisions during this programmed proliferation.¹³⁷ During their proliferative expansion and differentiation in the SLO, the responding T cells lose cell-surface adhesion molecules (e.g., CD62L) and receptors (e.g., CCR7) necessary for naïve T-cell circulation, and they upregulate the expression or express *de novo* adhesion molecules (e.g., the $\beta 2$ integrin, LFA-1, and $\beta 1$ integrin, very late antigen 4 [VLA-4], respectively), and chemokine receptors (e.g., CCR5, CXCR3) essential for effector T cells to localize to sites of inflammation.¹⁶⁵

At the end of the proliferation/differentiation sequence, most activated antigen-specific effector T cells will upregulate S1P1R and exit the SLO (through the efferent lymphatics in the case of T cells responding in the draining LN), enter the circulation, and traffic to the site of infection/inflammation. The homing of activated T cells is controlled by chemokines released by innate immune cells (as well as by epithelial and endothelial cells and fibroblasts) at the site of inflammation/infection (e.g., CXCL9 [Mig/CXCL9 (Monocline Induced by Gamma interferon)], CXCL10 [IP-10 (Interferon gamma induced Protein-10)], and CXCL11 [I-TAC (Interferon-inducible T cell Alpha Chemoattractant)] for CXCR3; and CCL3 [macrophage inflammatory protein-1 α ; MIP-1 α] and CCL4 [MIP-1 β] for CCR5). This homing is also controlled by the inflammation-induced upregulation of integrin ligands (e.g., intercellular adhesion molecule-1 [ICAM-1] for LFA-1, and vascular adhesion molecule [VCAM] for VLA-4) and adhesion receptors (P-selectin, E-selectin) on endothelial/epithelial cells at these sites.

The generation of effector T cells in the SLOs responding to infection can occur in as few as 5 to 7 days in both experimental models and human viral infection.⁶⁸ Given the rapid replication of most viruses, it is obviously essential to get specific T cells activated and mobilized as soon as possible through the concentration of antigen and the accumulation of the rare antigen-specific T cells in the SLO, followed by rapid proliferative expansion/differentiation of these cells into effectors in the SLO. The rapid induction of an adaptive immune response to virus infection is not a foregone conclusion, however. The process of T- and B-cell activation can be delayed for weeks to months in the case of infection with viruses such as HIV and HCV, which induce chronic infection.^{111,187} In these instances, the virus has the capacity to suppress/delay the induction of the adaptive immune response.

The process of naïve B-cell activation in the SLOs is similar to that of naïve T-cell activation. In the case of B-cell responses to viruses and other T cell-dependent antigens, however, antigen-specific CD4⁺ T cells play a critical role in driving B-cell activation/differentiation. As with naïve T cells, naïve B cells enter the LN through the HEV; unlike T cells, however, the B cells migrate from the paracortical (T-cell rich) area of the LN and into the B cell-enriched LN cortical follicle. This migration is controlled by the chemokine CXCL13, produced by a stromal cell type resident in the follicle (called a *follicular DC* because of its dendritic morphology, but not of hematopoietic origin). CXCL13 is the ligand for CXCR5 chemokine receptor that is constitutively expressed by naïve B cells. If the B cell does not encounter antigen in the follicle, it will ultimately migrate out of the cortical follicle to the medulla, then enter the efferent lymphatics, and rejoin the circulating pool of B cells in the bloodstream.

The B cells that display a BCR antigen receptor (i.e., the cell-surface membrane-bound form of the immunoglobulin molecule that recognizes antigen) for an antigen present in the LN would encounter this antigen immediately after migrating out of the HEV in the parafollicular (T-cell rich area) of the LN. In the case of viral antigen, the relative contribution of free virus, soluble viral proteins, and viral proteins transported by migrant DC/macrophages from the infection site to the reservoir of antigen present in the SLO and available to specific B cells is not certain. However, it has been recently appreciated that structures (i.e., conduits) within the SLO (in the case of LN) direct particulates like viruses and soluble proteins directly to regions of naïve B-cell accumulation in the SLOs.¹²⁵ Binding of antigen to the BCR (i.e., cross-linking cell surface immunoglobulin) provides the initial stimulus (signal 1) for specific B-cell activation. Signal 1 delivery halts the constitutive migration of the B cell from the paracortical T-cell zone to the LN follicle, and activates the chemokine-dependent migration of the B cells to the junction between the T-cell zone and the follicle. The strength of signal 1 can be greatly enhanced if the BCR co-receptor complex²⁰¹ is ligated simultaneously with the BCR by interaction with complement components bound to antigen or antigen-antibody complexes. In addition, cross-linking of the immunoglobulin receptor induces internalization of the antigen-immunoglobulin complex into an endosomal compartment where the antigen is fragmented and associates with MHC class II molecules that are constitutively expressed by B cells. The antigen/MHC class II complexes are then cycled to the B-cell surface, where they are available for recognition by antigen-specific CD4⁺ T cells. Another consequence of signal 1 delivery (by antigen to B cells) is CD40 upregulation. The CD4⁺ T cells, which interact with antigen-stimulated B cells, are themselves activated by prior encounter with antigen/MHC class II complexes on APC (i.e., mature, antigen-bearing DC), and have upregulated CD154 (CD40L) expression. The activated antigen-specific CD4⁺ T cells recognize the antigen/MHC complexes on the antigen-stimulated B cells, and deliver signal 2 to the B cells in two forms: interaction of CD40L (on T cells) with CD40 (on B cells), and the release of T-cell-derived cytokines (notably, IL-4, IL-21, and/or IFN- γ) whose synthesis is triggered in the CD4⁺ T-cell TCR recognition of antigenic peptides displayed by the B cells. Antigen-activated CD4⁺ T cells in LN may support B cell responses by differentiating into so-called T follicular helper (T_{FH}) cells. These activated CD4⁺ T cells appear to represent a distinct CXCR 5⁺/PD-1⁺ CD4⁺ T-cell subset, the generation of which is in part regulated by IL-6 produced within the responding LN. The cells secrete IL-21 in response to TCR engagement and also express CD154 (CD40L). The interaction of the T_{FH} with the naïve parafollicular B cells through CD40 engagement (on B cells) by CD40L on the T cells, and IL-21 signaling through its receptor on naïve T cells helps support the formation of B-cell germinal centers.

The fully activated (signals 1+2⁺) B-cell lymphoblasts undergo programmed proliferation after migration to the follicles to produce germinal center, which are follicular structures consisting primarily of responding/proliferating B-cell lymphoblasts. The proliferation/differentiation of the germinal center B-cell lymphoblasts results in the formation of antibody-secreting plasma cells, which migrate from the LN to the sites of infection/inflammation, and more importantly to the bone marrow where the plasma cells serve as a depot of long-lived antibody-secreting cells.¹⁶⁷ B cells that encounter antigen

without CD4⁺ T-cell *help* (i.e., receive signal 1, but not signal 2) are capable of producing specific secreted antibodies; however, these antibodies will be of the immunoglobulin M (IgM) isotype and of low affinity. The isotype switch of antibody production from IgM to the IgG, IgA, and so on isotypes, as well as, the process of antibody affinity maturation requires T-cell help (signal 2).¹⁶⁷

VIRAL ANTIGEN RECOGNITION BY B CELLS

Viral antigens are found on virions, on virus-infected cells, as soluble molecules produced by virally infected cells, and as breakdown products from virions and infected cells. These antigens can be recognized by antibodies in soluble form in plasma or tissues and by antibodies on the surface of B cells (i.e., BCR). If the individual has had previous exposure to viral antigen(s) through infection or vaccination, then specific soluble high-affinity antibodies will likely be present in the plasma. A minority of these antibodies will be reactive with viral antigens presented on virions and virally infected cells and able to function antivirally. Many will be directed to a range of nonsurface viral antigens; that is, they will be functionally inert, but may be useful in the diagnosis of viral infection. In the case of prior infection or vaccination, memory B cells that express specific antibody will be activated on contact with viral antigen, leading to the production of soluble, specific high-affinity antibody and the increase of specific serum antibody levels. In the absence of a previous encounter with viral antigen, antibodies on the surface of naïve B cells will bind antigen with relatively low affinity, setting in motion antibody affinity maturation and class-switching processes, which are discussed below.

NATURE OF B-CELL EPITOPES

Most of what is known about how antibodies recognize antigens has been determined from studies on the interaction of soluble antibodies or antibody fragments with antigen.^{61,208,308} Given that B-cell surface antibody is essentially identical to soluble monomeric antibody, with an extra segment ensuring membrane localization, the conclusions should apply broadly to cell surface antibody. Antibodies recognize molecular shapes, termed epitopes, on the surface of antigens. The antibody-combining site makes multiple contacts with the surface of the antigen to form complementary surfaces. The more complementary these surfaces are to one another—in terms of geometry and chemical character—the more favorable interactions will be formed between the antibody and antigen and the higher will be the affinity of the antibody for antigen. The affinity of the antibody for the antigen is one of the most important factors in determining the efficacy of the antibody *in vivo*.

The antibody-combining site is made up of residues contributed primarily from six highly variable segments or loops referred to as hypervariable loops or complementary determining regions (CDRs). The site can vary greatly in shape and character depending on the length and characteristics of the CDRs. Generally, most or all of the CDRs contribute to antigen binding, but their relative contributions vary. The heavy chain CDRs (particularly the third heavy chain CDR [CDR H3]) tend to contribute disproportionately to antigen binding. The CDR H3 in human antibodies can be very long, with

distinctive shapes such as fingers and hammerheads that contact viral epitopes. The combining site of antibodies against smaller molecules such as carbohydrates and organic groups (haptens) are often more obviously grooves or pockets, rather than the extended surfaces typically found in antiprotein antibodies.

On the antigen, epitopes come in as many different shapes and sizes as do antibody-combining sites. The area of antigen that contacts antibody, referred to as a footprint, is typically between about 400 and 1,000 Å². All antibodies recognize a topographic surface of a protein antigen. Most usually, key residues in the epitope will arise from widely different positions in the linear amino acid sequence of the protein because of the manner in which proteins are folded. The linear sequence typically traverses from one side of the protein to the other a number of times. Such epitopes are described as discontinuous. Occasionally, key residues arise from a linear amino acid sequence. In such cases, the antibody may bind with relatively high affinity to a peptide incorporating the appropriate linear sequence from the antigen. Furthermore, the peptide may inhibit the antigen binding to the antibody. The epitope in such cases is described as continuous. An example of a continuous epitope would be a loop on the surface of the protein for which an antibody recognized successive residues in the loop. It should be noted, however, that an antibody that recognizes a continuous epitope does not bind a random or disordered structure. Rather, it recognizes a defined structure that is found in the complete protein but can be readily adopted by the shorter peptide.

ANTIGENICITY AND IMMUNOGENICITY

A clear distinction is seen between the ability of an epitope to be recognized by antibody (antigenicity) and its ability to stimulate an antibody response when presented to a host antibody system (immunogenicity). A number of factors appear to be involved in how well a given epitope elicits an antibody response. Perhaps one of the most important factors is the accessibility of the epitope on the protein surface. Loops that protrude from the surface of the folded protein tend to elicit particularly good antibody responses. Figure 9.2 shows epitopes on the hemagglutinin (HA) protein from the surface of the influenza virus, with those at the “top” of the molecule distant from the viral membrane and most accessible to antibody. Natural infection and classical vaccination strategies typically induce antibodies to the top of the HA and mostly to variable regions that are therefore strain specific. Changes within these immunodominant variable regions allow neutralization escape and dictate repeated annual influenza vaccinations to provide robust protection to large populations. More conserved regions in the stem region of the HA appear to induce weaker antibody responses, but if these could be presented in a more immunodominant format they might induce broadly neutralizing antibodies and thereby provide a universal influenza vaccine that would replace the current annual vaccines. HIV is another virus in which highly exposed variable regions on the viral surface glycoprotein are immunogenic.³¹³ Following primary infection, it takes some time (weeks) for neutralizing antibodies to reach a level where they interfere with virus replication.^{229,303} These antibodies are typically elicited to exposed variable loops on the virus. While these antibodies are being elicited, the virus has diversified (i.e., it has become a swarm

FIGURE 9.2. Neutralizing epitopes on influenza hemagglutinin (HA).

The epitopes were determined from crystal structures of neutralizing Fab fragments in complex with HA. The viral membrane is at the **bottom** of the figure. Most of the epitopes toward the top of the HA molecule are relatively variable in different influenza strains. The epitopes defined by the antibodies CR6261 and CR8020 in the stem of the HA molecule are conserved and might be targeted by a universal influenza vaccine. (Courtesy of Damian Ekiert and Ian Wilson.)

of related viruses through the errors associated with reverse transcription of this RNA retrovirus). Among this swarm is a virus that has sequence changes in the epitopes targeted by the neutralizing antibody response that allows it to escape from the response. This new virus becomes predominant. Eventually, a response is mounted to this virus and a second new virus emerges and so on. The antibody response chases the virus over many years but never appears to gain control.

An important consideration in relation to viral surface antigens and immunogenicity is the spacing of the antigens on the virion surface.¹² It is well established that haptened polymers, in which the haptens are spaced at 5 to 10 nm, can induce antibody responses in the absence of T-cell help. For vesicular stomatitis virus (VSV), in which the G protein is found in a highly organized quasicrystalline state on the virion surface, a strong immunodominant T-cell-independent neutralizing antibody response is induced by infection. A poorly organized recombinant form of VSV-G expressed in micelles induces a weaker B-cell response that is partially T-cell dependent. Soluble VSV-G alone, in the absence of adjuvant, fails to induce a B-cell response.

GENERATION OF THE PRIMARY B-CELL REPERTOIRE

The humoral immune system first senses the presence of novel viral antigens through the interaction of B-cell surface

antibody (monomeric IgM and/or IgD) with antigen. Individual B cells possess multiple BCRs of identical specificity, which when occupied by antigen, are activated to divide and differentiate. The final results include the production of large amounts of specific, soluble high-affinity antibody and the generation of memory B cells that can be readily triggered to produce high-affinity antibody on repeated encounter with viral antigen.²²⁶ The first encounter of viral antigen is with the primary B-cell repertoire of the individual. This repertoire is large, allowing recognition with low affinity of essentially any molecular shape and, therefore, any viral variant. It is produced in B cells by recombination of a limited set of germline segments.^{121,134,169,175} Hence, an individual's primary repertoire is unique to that individual and is in a constant state of flux. Briefly, the variable regions of antibody heavy and light chains are produced by V(D)J recombination in which numerous unique immunoglobulin genes can be made by joining different combinations of the V, D, and J segments at the heavy, and V and J segments at the light, chain loci. In humans, the potential heavy chain repertoire is approximately $50 \text{ VH} \times 27 \text{ DH} \times 6 \text{ JH} = 8 \times 10^3$ different combinations. Similarly, approximately $165 (33 \text{ V}\lambda \times 5 \text{ J}\lambda)$ and $200 (40 \text{ V}\kappa \times 5 \text{ J}\kappa)$ different combinations exist, for a total of 365 light chain (λ and κ) combinations. If we consider that each heavy chain could potentially pair with each light chain, then the diversity of the immunoglobulin repertoire is of the order of 10^6 possible combinations. Further diversity (junctional diversity) is generated because the joining of the V, D, and J gene segments is imprecise.

Although mice and humans use combinatorial and junctional diversity as a mechanism to generate a diverse repertoire, in many species, including birds, cattle, swine, sheep, horses, and rabbits, V(D)J recombination results in assembly and expression of a single functional gene.^{169,179} Repertoire diversification is then achieved by gene conversion, a process in which pseudo-V genes are used as templates to be copied into the assembled variable region exon. For example in the chicken, during B-cell development in the bursa of Fabricius, rapidly proliferating B cells undergo gene conversion to diversify the antibody repertoire. Stretches of sequences from germline variable region pseudogenes, located upstream of the functional V genes, are introduced into the VL and VH regions. This process takes place in the ileal Peyer's patches of cattle, swine, and horses, and in the appendix of rabbits.

B-CELL ACTIVATION BY VIRAL ANTIGENS

B cells can recognize and respond to both soluble and membrane-bound viral antigens, although it is likely that, in vivo, the most relevant interaction is with antigen on the surface of APCs.^{14,15} The encounter of viral antigens with BCR has two consequences. First, a signal is transmitted into the B cell that is amplified via intracellular pathways and results in the activation of transcription factors such as nuclear factor- κ B (NF- κ B) and AP-1. These factors act to induce specific gene transcription promoting B-cell proliferation and differentiation. Second, the BCR delivers viral antigens to intracellular sites where they are proteolytically cleaved and some viral peptides are bound to MHC class II molecules. The peptide/MHC II complexes are returned to the B-cell surface where

they can be recognized by viral-specific TCR on specialized CD4⁺ T cells (T helper cells), known as TFH or T follicular helper cells.^{52,200} These TFH cells are then stimulated to produce cytokines and provide surface costimulatory molecules that promote B-cell proliferation and act on later generations of these B cells to promote differentiation to antibody-producing and memory B cells. Some viral antigens, as described above, can activate B cells directly in the absence of T-cell help (so-called T-independent antigens).

Cell signaling from the BCR occurs when multiple antigen contacts lead to clustering of cell surface IgM molecules.²¹⁹ In the BCRs, IgM monomer is associated with a heterodimer of membrane-bound Ig α and Ig β molecules, which bear immunoreceptor tyrosine activation motifs (ITAM) on their cytoplasmic domains. Following BCR clustering, tyrosines in the ITAM become phosphorylated to trigger a series of events that eventually lead to activation of transcription factors. Signaling by the BCR is modulated by co-receptors, most notably Fc receptor IIB for IgG (FcR γ IIB) and CD19. FcR γ IIB is a potent inhibitor of B-cell signaling¹⁹⁷ by reversing protein kinase activities and by inhibiting the formation of BCR microclusters. CD19 is an activating coreceptor⁶⁴ that functions to recruit activating molecules to the BCR. In addition, CD19 occurs on the surface of B cells alone and is linked to CD21, a receptor for the complement fragment C3d. If, following complement activation, C3d has been linked to viral antigen or to antibody-virus complex, the co-receptor complex can be linked to the BCR and BCR activation enhanced. The involvement of complement can be crucial in the development of normal B-cell memory responses (see below). Mice with deficiency in C3, C4, or CD21/CD35 and infected with HSV show a reduction in specific IgG and germinal centers compared to normal mice.⁵⁹

The interaction of B cells with viral-specific TFH cells in lymphoid tissue leads to B-cell activation and proliferation and differentiation. It is important to note that the B-cell surface antibody and the TCR must recognize epitopes from the same molecular complex for the help signal to be delivered and B-cell activation to occur. Therefore, a B cell that is expressing surface antibody to the surface protein of a virus could be activated by a T helper cell expressing a TCR to an internal viral protein if antigen challenge involved whole virions.²⁴¹ A subunit vaccine consisting only of the envelope protein could not obtain help from such a T helper cell. The process is as follows. The B cell binds a virion through antibody recognizing surface protein. The whole virion is internalized and degraded, and peptides displayed on MHC class II molecules are carried to the B cell surface. Specific TFH cells that have previously been primed by DCs recognize the peptide-MHC class II complex on B cells through specific TCRs.⁴⁴ Antigen recognition results in T-cell adhesion to the B cell and the provision of "help" to the B cell via a range of transmembrane costimulatory receptors and cytokines. TFHs are highly enriched for selective expression of an array of cell surface molecules, reflecting their specialized role for cell-cell interaction with B cells.⁵² The most critical cell-cell interaction is CD40-CD40L. CD40 on B cells engages CD40 ligand (denoted CD40L and also known as CD154) on TFH cells, driving B-cell proliferation. The combination of B- and T-cell interactions and locally released cytokines can further enhance B-cell proliferation or direct differentiation, depending on the signals provided by

the TFH cell and the cell surface molecules expressed by the B cell. Of interest, the process of shared CD4 T-cell help to B cells specific for a different viral protein may occur only for small viruses, as the B cell and antibody responses to infection with vaccinia virus (a large poxvirus used as the smallpox vaccine) are strictly dependent on matched CD4 T-cell help.²⁵⁴ This likely reflects a limit on the pathogen or particle size that a B cell can endocytose whole.

There are two pathways for B cells that have contacted specific T cells. In the first, after several rounds of proliferation, B cells differentiate into plasma cells in extrafollicular foci¹⁶⁸ and secrete relatively large amounts of soluble antibody to the virion surface protein of our example. This antibody is encoded by the unmutated germline repertoire and of the IgM isotype or class-switched to IgG or IgA. The plasma cells are short-lived with a lifespan of a few days. This early antibody is believed to be important as a first-line humoral response against viral infection.

In the second pathway involving germinal centers (GCs) in lymphoid tissues (see Section 2), the quality and versatility of the antibody to the virion surface protein can be improved by affinity maturation and isotype switching.^{40,73,154,166,172,182,188,195} In GCs, B cells divide very rapidly, every 6 to 8 hours. CD4 T cells are required for the formation and maintenance of GCs. GC TFH cells provide signals that regulate maintenance of GC B cells and GC B-cell differentiation into plasma cells and memory B cells.⁵² GC TFH cells critically stimulate somatic hypermutation and selection of high affinity clones. Somatic hypermutation¹⁷⁷ involves the introduction of nontemplated point mutations into V regions of the rapidly proliferating B cells at a rate on the order of 1×10^{-3} mutations per base pair per generation, which is approximately 10^6 times higher than the mutation rate of cellular housekeeping genes. The enzyme activation-induced cytidine deaminase (AID) has been demonstrated to be essential for somatic hypermutation. AID is a cytidine deaminase capable of carrying out targeted deamination of C to U, and shows strong homology with the RNA-editing enzyme APOBEC-1. It seems that AID directly deaminates DNA to produce U:G mismatches that ultimately can result in sequence changes in the V regions. Selection from the array of B cells expressing slightly different mutated forms of cell surface antibody was thought to occur based directly on the ability of higher affinity clones to compete for antigen and receive stronger BCR signals and survive. More recently however,^{56,294} a somewhat different view has emerged in which B cells gather antigen as they move over the network of follicular DCs in GCs. Cells with the highest affinity for antigen acquire the most antigen, thereby leading to greater presentation of peptide/MHC II complexes to T cells, which in turn provide the requisite cytokine signals for B-cell survival and selection.

Isotype switching, in which the constant region of IgM is replaced by that of another isotype, also occurs in germinal centers. This might lead for example to a switch from IgM to IgG or IgA antibodies against a virion surface protein. Switching occurs through deletional DNA recombination events and involves repetitive DNA sequences or switch regions. The enzyme AID, described above, appears to be critically involved in the process. Cytokines such as IFN- γ and IL-17, which are expressed by germinal center TFH cells in a context-dependent manner, control appropriate isotype switching to different pathogens.

The B cells surviving the germinal center differentiate into plasma cells or memory B cells.^{97,171,182,304} Plasma cells accumulate in the spleen or draining lymph nodes during the early stages of acute infection, but as the immune responses subside, the majority of plasma cells are found in the bone marrow.^{11,124,267,318} These cells no longer express surface antibody but are committed to the secretion of soluble antibody—up to 10,000 antibody molecules per second.^{113,118} Because the half-life of IgG is on the order of 1 to 3 weeks, but specific antibody can be present for many years after antigen exposure, it appears that plasma cells maintain serum antibody levels. A favored hypothesis is that plasma cells are very long-lived and continue secreting antibody long after antigen has disappeared (see below). The half-lives of antibody responses in humans to measles and mumps viruses for example are estimated at more than 200 years.⁶ Memory B cells can also last for many decades.^{54,319} Memory B cells maintain surface antibody but secrete little if any antibody, unless activated. They divide slowly if at all. B-cell memory is considered in greater detail below.

VIRAL ANTIGEN RECOGNITION BY T CELLS

The T-cell response to viruses is largely mediated by T cells that utilize the TCR $\alpha:\beta$ chain heterodimer to recognize a foreign antigen. T cells, which employ the $\gamma:\delta$ chain complex (the gamma/delta cells), as well as certain rare TCR $\alpha:\beta$ expressing T cells with restricted variable α (or β) gene segment usage in TCR generation (e.g., NK T cells) have a less clearly defined role in the adaptive immune response to viruses (and will be briefly discussed below). The conventional TCR $\alpha:\beta$ T cells, which have left the thymus and populated the SLOs and bloodstream, express, along with their TCRs, either the CD4 or the CD8 co-receptor molecules. One defining feature of the response of these cells is that $\alpha:\beta$ antigen receptors recognize nonnative peptide fragments of foreign antigen (including viral polypeptides). Therefore, in contrast to the immunoglobulin receptor (BCR), which is sensitive to antigen conformation, T-cell recognition of antigen is insensitive to three-dimensional antigen structure. Furthermore, T-cell recognition of antigens (e.g., viruses) is limited primarily to the polypeptide constituents of the virus or, more precisely, to viral gene products expressed in infected cells (although some rare exceptions exist to this general rule, which are noted later in this chapter).

A second defining feature of the $\alpha:\beta$ TCR is that the antigen receptor recognizes these antigenic peptides bound to MHC molecules displayed on the surface of the antigen-containing (e.g., virus-infected) cells. Therefore, CD4⁺ and CD8⁺ T cells are restricted in their recognition of foreign antigen to cells displaying the foreign peptide complexed to the MHC molecule to which that T cell was selected during development in the thymus. This is the phenomenon of MHC restriction³²⁴ that defines antigen recognition by T cells. CD8⁺ T cells will recognize cells displaying the foreign antigen peptide bound to one of several distinct MHC class I molecules expressed on the cell surface. CD4⁺ T cells, likewise, are restricted in foreign peptide recognition by the cell surface MHC class II molecule to which the peptide fragment is bound.

The implications of MHC-restricted recognition of processed peptide fragments by T cells for virus recognition are immediate and profound. Conventional TCR $\alpha:\beta$ T cells

responding to virus infection will recognize infected cells and not free virions or soluble viral proteins. Therefore, the activation of naïve T cells and the expression of the effector activity of activated T cells responding to virus infection will be primarily mediated through cell-to-cell contact (i.e., contact between naïve T cells and APCs or the infected cell targets of effector T cells, such as epithelial cells). In addition, T cells have the potential to recognize any viral gene product (structural or nonstructural) that can be fragmented into peptides, and bound to/displayed by MHC molecules on the surface of infected cells. Consequently, CD8⁺ T cells will only recognize virus-infected cells that display peptide fragments of viral protein bound to cell surface MHC class I molecules, whereas CD4⁺ T cells will recognize only those cells in which display viral peptide/MHC class II complexes. The differences in the cell types that display MHC class I and II molecules, and the distinct mechanisms by which foreign polypeptides are processed (fragmented) and bound to/presented by MHC class I and II molecules determine how CD8⁺ and CD4⁺ T cells respond to virus infection.

The function of the MHC molecules is to bind peptide fragments from pathogens, and to display them on the cells harboring the pathogen for recognition by T cells expressing the appropriate (i.e., specific) TCR. The consequences of this MHC-TCR-dependent cell-cell interaction are almost always deleterious to the pathogen: virus-infected cells are killed; macrophages are activated to destroy intracellular bacteria living within their intracellular vesicles; and B cells are activated to produce antibodies that eliminate or neutralize extracellular forms of pathogens. The MHC locus is located on chromosome 17 in the human (chromosome 4 in the mouse), and extends over approximately 4 centimorgans of DNA ($\sim 4 \times 10^6$ base pairs). Two properties of the MHC locus product make it difficult for pathogens to evade the adaptive immune response. First, the MHC locus is polygenic.²⁵⁸ It encodes several different MHC class I and II gene products, and these differences in nucleotide/amino acid sequence control the range of peptide fragments that an individual MHC molecule can bind, so that every individual possesses a set of MHC molecules with a different range of peptide-binding specificity. Second, the MHC locus is highly polymorphic. Multiple versions (alleles) exist of each MHC gene product expressed in the population as a whole. In fact, the MHC genes are the most polymorphic genes in the human genome.²⁵⁸

The MHC locus contains three major classes of genes: class I, II, and III. The MHC class I and II genes (and their products) were first identified because of their critical role as targets in graft rejection. Hence, the name for the human MHC locus, HLA, (for human leukocyte antigen locus), and H-2 (histocompatibility-2 locus) for the corresponding genes in the mouse. The MHC class I genes (or more precisely MHC class Ia genes) consist of eight exons and encode a 45-kD protein containing three external domains (α_1 , α_2 , α_3), along with a membrane-spanning segment and a short cytoplasmic tail. The α_1 and α_2 domains fold to form a molecular platform on the upper, outer surface of the molecule, with a *groove* or cleft to accommodate peptide fragments from pathogens.⁸³ Amino acid differences in the α_1 and α_2 domains among several class I molecules encoded within the MHC locus genes of an individual and between the numerous alleles of the gene encoding a given MHC class I gene

product among humans dictate the types of peptides that can be accommodated in the peptide-binding groove. The α_3 domain contains the site for the binding CD8 molecules to the MHC class I. The MHC class I molecule is a heterodimer consisting of the MHC encoded 45-kD heavy (H) chain complexed noncovalently with a non-MHC locus-encoded small molecule, β -2 microglobulin (β -2M), which interacts with the H chain α_3 domain. Stable cell surface expression of the MHC class I molecule usually requires β -2M association. Importantly, MHC class I molecules are expressed at varying levels on most cells of the body, with neurons being a notable exception.²¹⁸ The expression levels of class I molecules on the cell surfaces can be upregulated by exposure of the cell to inflammatory mediators (e.g., type I and II IFN, TLR agonist, and so on).^{85,141} Therefore, the T cells that recognize peptide/MHC class I complexes (i.e., the CD8⁺ T cells) have the capacity to survey most body cells and interact with/destroy cells displaying the appropriate peptide/MHC class I complex. Three class I genes (more precisely, three class Ia genes) exist in the human: HLA-A, HLA-B, and HLA-C (H-2K, H-2D, and H-2L in the mouse), and each gene is polymorphic (i.e., displays multiple different alleles) within the human population.

The MHC class II molecules are also heterodimers, consisting of two chains (α and β), each encoded by a separate gene. These genes have a similar exon-intron structure, with the class II α chain genes encoding two extracellular domains (α_1 and α_2), and the class II β chain gene likewise encoding two extracellular domains (β_1 and β_2). The α_1 and β_1 domains of the class II molecules interact to form a molecular platform with a groove to accommodate the foreign peptide, which is like the α_1 and α_2 domain of the class I molecule on the upper outer surface of the molecule and, therefore, available for recognition by the TCR on CD4⁺ T cells. The CD4 molecule on the T cell interacts with the surface of the β_2 domain, distal to (away from) the TCR binding site. The class II heterodimer is anchored to the cell membrane by transmembrane segments of both chains, and each chain contains a short cytoplasmic tail. In contrast to class I molecules, the expression of class II molecules is largely restricted to immune system cells: B cells, macrophages, DCs, and activated T cells in the human (and to a lesser extent, for activated T cells in the mouse), as well as specialized epithelial cells in the thymus and type II alveolar epithelial cells in the lungs. The expression of MHC class II molecules on these cells can be upregulated by cytokines (in particular, IFN- γ)⁶⁴; evidence indicates that certain somatic (nonimmune) cells can be induced to express MHC class II molecules in response to inflammation.⁸⁵ Three pairs of MHC class II α and β chain genes exist, which are called HLA-DR, HLA-DP, and HLA-DQ (two pairs in the mouse: H-2^{I-A} and H-2^{I-E}). In some instances, the DR cluster contains the genes for two β chains (DR β_1 , DR β_2), each of which can pair with the DR α chain. Again, multiple alleles exist for each gene pair. The amino acid differences among the alleles are localized primarily to the α_1 and β_1 domains, where these residue differences control the range of foreign peptide bound by the various MHC class II allelic gene products.⁶⁶

Although both MHC class I and II molecules are similar in structure and function (i.e., presenting foreign peptides), the difference in the cellular distribution of these molecules points to the role of the T-cell subsets (CD8⁺ and CD4⁺ T cells)

that recognize these molecules in the function of the adaptive immune system. For example, viruses have the potential to infect most nucleated body cells. Because these cells also express (to a varying degree) MHC class I molecules, they would be susceptible to recognition and destruction by activated effector T cells that are restricted by class I molecules in antigen recognition (i.e., CD8⁺ T cells). This simple association suggests an important role of CD8⁺ T cells in eliminating virus-infected cells and recovery from infection.⁷⁰ By contrast, MHC class II molecules are displayed primarily on cells of the immune system. Therefore, the main role of CD4⁺ T cells, which recognize these molecules and the bound foreign peptides, is to activate and regulate the effector response of the other immune cells (e.g., the recognition by activated CD4⁺ T cells of peptide/MHC class II complexes on B cells to stimulate antibody production, the recognition of peptide/MHC class II complexes on macrophages harboring pathogens within intracellular vesicles to stimulate macrophage activation and pathogen destruction, and the recognition of peptide/MHC class II complexes on DCs to stimulate cytokine production during the induction of adaptive immune responses).

Of course, the ability of CD8⁺ and CD4⁺ T cells to interact with cells displaying foreign peptide/MHC complexes also depends on the ability of these foreign antigens to provide peptides to complex with the MHC class I and II molecules. As will be discussed, the pathways by which foreign antigens gain access to and charge MHC class I and II molecules is distinctly different, and dictates the contribution of CD8⁺ T cell and CD4⁺ T cells in the adaptive immune response to invading microorganisms.

ANTIGEN PROCESSING AND PRESENTATION TO T CELLS

The pathways of antigen processing and peptide presentation by MHC class I and II molecules to CD8⁺ and CD4⁺ T cells are historically called the *endogenous* and *exogenous* presentation pathways. In the most basic terms, protein antigens, such as viral polypeptides, which gain access to the cell cytoplasm, have the potential to efficiently enter the MHC class I

processing/presentation pathway—that is, produce peptides that can charge MHC class I molecules in the cells for subsequent recognition by antigen-specific CD8⁺ T cells. During viral infection, access to the cell cytoplasm is perhaps most effectively achieved by infection of the cell that is by *de novo* synthesis of viral gene products.⁹² This endogenous presentation pathway (i.e., infection of the cells) is the typical way that most virus-infected body cells are sensitized for recognition by activated CD8⁺ T cells. Certain bacteria (e.g., *Listeria monocytogenes*, *Salmonella*) and parasites (e.g., malaria) that can gain access to the infected cell cytoplasm can provide protein antigens, which enter the class I presentation pathway, as can strategies that introduce proteins directly into the cytosol of cells (e.g., liposome-cell fusion).^{99,306} Certain cell types that act as professional APCs (most notably, DCs) have the capacity to take up soluble or aggregated antigenic material (i.e., apoptotic, infected cell debris), and process/present antigenic peptide by MHC class I molecules to CD8⁺ T cells by one of several different cross-presentation mechanisms that have been elucidated.²⁵⁹

Protein antigens, both soluble and particulate (e.g., bacteria, virions), which are internalized into the endocytic compartment of cells expressing MHC class II molecules, have the potential to enter the class II processing/presentation pathway and charge MHC class II molecules for recognition by CD4⁺ T cells. This exogenous presentation pathway (i.e., uptake from without) characterizes the handling of soluble antigen (e.g., intact, inactivated virions and subunit vaccines and extracellular bacteria) by the adaptive immune system, leading to the production of activated CD4⁺ T cells and antibodies. Any foreign protein (including a viral membrane glycoprotein) expressed on an infected MHC class II-expressing cell can enter the class II pathway, however, if it can gain access to the endocytic compartment where processing/presentation occurs (Table 9.4).

This somewhat simplified distinction between endogenous (class I) and exogenous (class II) processing/presentation pathways highlights the importance of antigen presentation in dictating the action or effector activity of the T-cell arm of the adaptive immune system. Generally, pathogens that gain access to the cell cytoplasm will generate peptide/MHC class I complexes and trigger a CD8⁺ T-cell response, whereas pathogens/pathogen

TABLE 9.4 Features of Viral Antigen Processing by the Major Histocompatibility Complex Class I and Class II Presentation Pathways

	Location	Proteolysis	MHC loading peptides
MHC Class I Pathway	Cytoplasm ^a	Proteasome ^b neutral pH	Endoplasmic reticulum
MHC Class II Pathway	Endosome ^c	Acid proteases low pH	Endosome ^d

^aViral proteins gain access to the cytoplasm by (a) *de novo* expression of viral proteins in infected cells; (b) direct virus-cell fusion at plasma membrane or in endosomes; (c) in specialized antigen-bearing presenting cells (APCs) (i.e., dendritic cells) by phagocytic uptake of virus or virus-infected cellular material into endosomes followed by endosome–endoplasmic reticulum (ER) fusion with or without retrograde transport of viral proteins into the cytoplasm.

^bOther proteases in the cytoplasm and ER can modify the length of the viral peptide fragment produced by the proteasome before or after transport of the peptide into the ER by the transporter associated with antigen processing (TAP) transporter complex.

^cViral proteins in the form of virions and soluble and membrane-associated viral proteins must gain access to the endosome for fragmentation and binding to major histocompatibility complex (MHC) class II molecules.

^dNewly synthesized MHC class II molecules are blocked from loading peptides in the ER by the class II-associated invariant (Ii) complex which is dissociated from class II molecules in the endosome by step-wise proteolytic cleavage of the Ii chain.

products that remain exclusively in the specialized endocytic compartment of MHC class II-expressing cells will typically trigger a CD4⁺ T-cell response. The steps in the processing (fragmentation) of polypeptides into peptides, as well as the transport and interaction of peptides with MHC molecules, not surprisingly, are different in the class I and class II presentation pathways. Examination of these steps merits review because viruses have developed strategies to suppress the T-cell response by subverting the steps along these pathways.

ANTIGEN PRESENTATION BY THE MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I PATHWAY

Antigenic peptides usually bind newly synthesized MHC class I molecules in the endoplasmic reticulum (ER) of the antigen-bearing/infected cells. Therefore, in most cell types, the foreign polypeptide must be fragmented in the cytoplasm, transported from the ER, and associate with a newly synthesized class I 45-kD heavy chain/ β_2 M chain complex before transport of the MHC/peptide complex from the ER through the secretory pathway to the cell surface (Fig. 9.3). Antigenic peptide production through fragmentation of cytosolic proteins is primarily carried out by the multisubunit, multicatalytic 20S/26S proteasome complex present in the cell cytoplasm.²³¹ This enzyme complex accounts for most of the cytosolic protein degradation in all cells, and the proteasome is probably responsible for the generation of most self-peptides involved in T-cell selection in the thymus through the turnover (degradation) of cellular proteins in the thymic cortical epithelial cells and medullary DCs. Two important sources of proteasome substrates are newly synthesized self- or foreign (e.g., *de novo*) expressed gene products, such as viral proteins in an infected cell and preformed foreign microbes/microbial proteins that have gained access to the cell cytoplasm. The proteasome recognizes and degrades polyubiquitinated proteins. This protein tagging involves the sequential action of the ubiquitin-activating enzyme (E3), several ubiquitin-conjugating enzymes (E2), and substrate-specific ubiquitin ligases (E3)²³¹ to form the polyubiquitinated substrate of the proteasome. Some evidence suggests that enhancing ubiquitination of a protein may increase the amount of antigenic peptides generated for loading into MHC class I molecules. Furthermore, a significant fraction of newly synthesized proteins are ubiquitinated during the normal turnover of cellular protein, and evidence suggests that defective ribosomal translation products (i.e., products of premature ribosome termination and/or misfolded translation products) are a major source of the protein substrates for MHC class I peptide epitopes.³¹⁶ Therefore, the rate of protein synthesis rather than turnover or expression level would be critical for the loading of MHC I molecules with appropriate antigenic peptides. Such a strategy favors the generation and recognition of newly synthesized viral proteins in infected cells.

The core proteasome cleaves polypeptide substrates after hydrophobic and basic residues.²⁵⁶ Exposure of cells to certain cytokines (particularly, IFN- γ) induces the expression of three new proteasome subunits: b1i, b5i, and b2i (formally called LMP-2, LMP-7, and MECL-7, respectively). These subunits

replace existing subunits in the core proteasome, producing a second proteasome form, the immunoproteasome present in IFN-treated cells.³¹⁴ This replacement of the constitutive proteasome subunits with these inducible subunits changes the proteasome cleavage specificity, thereby increasing the cleavage of polypeptides after hydrophobic and basic residues and decreasing the cleavage after acidic residues (i.e., peptides with acidic C-termini). This is noteworthy because MHC class I molecules preferentially bind peptides (in an MHC class I allele-dependent manner) with hydrophobic or basic *anchor* residues at their C-termini.²⁹

Two of the IFN- γ -inducible proteasome subunits, b1i and b5i, are encoded by genes within the MHC locus,²⁵⁸ suggesting a strong evolutionary selective pressure for the immunoproteasome in MHC function. IFN- γ also increases the production of antigenic peptides by inducing the expression of a multisubunit proteasome adaptor complex PA28 which, on binding to the ends of the core proteasomes/immunoproteasome cylinder, increases the peptide efflux rate from the proteasome. Therefore, a cytokine product, IFN- γ , produced by an innate immune cell type (NK cells) or adaptive immune effector cells (antigen-specific CD4⁺ effector T cells) can enhance the display of antigen peptide fragments recognized by effector CD8⁺ T cells. Proteasomes generate peptides 3 to 20 amino acids (a.a.) in length.⁹³ Studies in which peptide fragments bound to MHC class I molecules isolated from cell surfaces were extracted and analyzed, however, revealed that these class I-bound peptides, in general, are 8 to 10 a.a. in length. Therefore, the proteasome peptide products that have the appropriate C-termini for MHC class I binding must also undergo cleavage at their N-termini. Several cytosolic (and one ER resident) aminopeptidases have been implicated in carrying out this process.^{93,126,159} N-Terminal trimming in the ER of transported peptides having an extended (greater than 8–10 a.a.) length is carried out in this compartment by the ER-associated amino peptidase (ERAAP). One cytosolic peptidase, tripeptidyl peptidase II (TPPII), may be capable of generating a limited range of peptides in the absence of proteasome function.¹⁴⁷ Overall, several studies have suggested that modifications of the proteasome core by inflammatory cytokines, combined with the action of cytosolic proteases, can affect antigenic peptide generation, including the production of antigenic peptides (in cells infected with several different viruses), the recognition of which by CD8⁺ T cells is dependent on these proteasome modifications and/or action of other cytosolic and ER proteases.^{261,290}

Peptides generated in the cytosol are transported to the ER by the heterodimeric transporters associated with antigen presentation (TAP)-1/TAP-2 protein complex. This transporter complex is located within the ER membrane, forming a pore/channel there.⁹⁶ Both proteins are members of the ABC family of ATP-dependent small molecule transporters, and are also encoded by genes mapping to the MHC locus. This transporter complex preferentially translocates peptide of 8 to 16 a.a. in length with hydrophobic or basic C-termini, and the TAP complex exhibits some restriction in transport efficiency of peptides with certain residues at the N-termini. Peptides gaining ER access through the TAP pore encounter the MHC class I peptide loading complex.²⁹¹

Newly synthesized MHC class I molecules must bind to β -2M and have a stably bound peptide (of self or foreign origin) in their peptide binding groove to retain the stable

FIGURE 9.3. Major histocompatibility (MHC) class I presentation pathway.

A: Following their co-translational translocation into the endoplasmic reticulum (ER), newly synthesized MHC class I forms a complex consisting of the ER scaffolding protein calreticulin (and calnexin—not shown), peptide and protein modifying enzymes (ERp57, protein disulfide isomerase [PDI]), the antigen presentation transporter associated with antigen presentation (TAP) transporter targeting molecule tapasin and a weak interaction with beta 2 microglobulin (β 2M). **B:** Processing/presentation through the classical MHC class I pathway requires that a target protein (e.g. viral polypeptide) gain access to the cell cytoplasm where it is ubiquitinated before fragmentation by the cytosolic protein complex, the proteasome. Peptide fragments are then transferred from the cytoplasm to the ER through the TAP transporter complex. The MHC class I complex is targeted to the TAP through the action of tapasin, and here the MHC class I and associated molecules come in contact with transported peptides. Peptides with the appropriate amino acid sequence (binding motif) and length/conformation (following modification by enzymes within the ER) will associate with the nascent MHC class I molecules/ β 2M to form a stable complexes. **C:** The new stable MHC class I/peptide/ β 2M complexes dissociate from scaffolding proteins and are transported via the secretory pathway to the cell surface where interaction with the CD8⁺ T-lymphocyte antigen receptor occurs.

conformation necessary for it to exit the ER.²⁹¹ Within the ER, nascent class I α chain molecules are bound to the ER chaperone, calnexin, until the 12-kD β -2M molecule binds, and calnexin is then replaced by the calreticulin scaffolding protein and the tapasin molecule (an MHC locus-encoded protein that forms a bridge between the class I α chain/ β -2M complex and the TAP transporter). The binding of calreticulin and tapasin to the nascent MHC class I molecule stabilizes the complex, allowing the partially folded class I/ β -2M complex to maintain a conformation (while it awaits a soluble peptide from the cytosol). The partially folded MHC class I molecule will selectively bind (select) only those peptides containing certain motifs; that is, common or conserved amino acid sequences distributed along the length of the peptide fragment. Each allelic form of the class I molecule has specificity for (binds to)

a peptide containing an MHC class I allele, a specific peptide binding motif. The ability of a specific MHC class I allelic variant to capture peptides displaying this conserved amino acid motif is dictated by the presence of polymorphic amino acid residues in the binding cleft formed by the α_1 and α_2 domains. A third component of the peptide loading complex is the ERp57 thio reductase and protein disulfide isomerase (PDI, which presumably catalyzes disulfide interchange in the class I α chain during peptide loading). In certain cells (e.g., macrophages, DCs), the aforementioned ER amino-peptidase, ERAAP,²⁴⁶ is associated with the loading complex, and acts to trim the N-termini of long peptide (i.e., ≥ 10 a.a.) down to size before final folding of the complex. After proper peptide loading and folding, the stable class I/ β -2M/peptide complex is freed from the chaperones, and migrates from the ER to the

cell surface. Note that in the uninfected cells, class I molecules still require a stably bound peptide to exit the ER and traffic to the cell surface. The source of these *antigenic* peptides is degraded cellular (self) proteins.²⁸

The classic MHC class I presentation pathway would appear to be restricted to proteins synthesized/retained in the cytosol. However, this is not the case. Numerous examples are found of secreted and membrane proteins/glycoproteins that contain peptides that are recognized by CD8⁺ T cells and, therefore, bound to MHC class I molecules. The most likely way that these proteins may be degraded is if the polypeptide chains are generated in the cytosol as defective or mistranslated ribosomal products, DRiPs.³¹⁵ Another way is retrograde transport of defective (misfolded) translation products that have been co-translationally translocated into the ER by the Sec61-dependent transport mechanism.¹ Sec61 normally acts in the translocation of the translation products of membrane-bound ribosomes into the ER, but can also shuttle intact (presumably defective) proteins in a retrograde fashion into the cytosol from the ER for degradation by the proteasome.¹ The unique ability of professional APCs (particularly CD8 α^+ and CD103⁺ cDCs) to “cross-present” cellular constituents/fragments of virus-infected cells may reflect the use of such a mechanism (i.e., uptake of virions, infected cellular material, and so on into endosomes followed by retrograde transport of this cargo into the ER) preferentially. Protein processing and peptide presentation to MHC class I molecules may also occur by direct loading peptides into the MHC molecules within endosomes, but the mechanistic basis for this processing pathway is poorly understood, and its *in vivo* significance for virus infection is uncertain.²⁵⁹

ANTIGEN PRESENTATION BY THE MAJOR HISTOCOMPATIBILITY COMPLEX CLASS II PATHWAY

Antigen processing and presentation along the MHC class II pathway differs from class I presentation in several ways (Table 9.4). First, the class II pathway focuses primarily on antigens (both soluble and particulate) that enter cells by endocytosis/phagocytosis, and are retained in endocytic compartments for subsequent processing (fragmentation) and loading of the peptide fragments into class II molecules. These endocytic compartments include early and late endosomes and, in certain instances, lysosomes.³⁰¹ Second, antigen fragmentation occurs in the low pH environment of the endosome (rather than in the neutral pH of the cytosol where proteasome-dependent MHC class I binding peptides are generated). Third, both newly synthesized and recycled (from the cell surface) MHC class II molecules can capture and present peptide fragments to CD4⁺ T cells. Fourth, unlike the strict length constraints (i.e., 8 to 10 a.a.) for peptides bound to MHC class I molecules, peptides bound to class II molecules are at least 13 amino acids long, and can be longer (i.e., up to 20 a.a.). As with the class I molecules, however, specific class II molecules (alleles) will selectively bind (select) peptides containing particular a.a. motifs (i.e., peptides containing common/conserved a.a. distributed along the length of the peptide). As for class I molecules, these peptide-binding motifs are dictated by the presence

of polymorphic a.a. residues in the class II binding cleft (which differ for each class II locus gene product allele). In summary, class II molecules bind peptides produced from soluble or particulate antigen taken up by endocytosis in the same low pH compartment where protein fragmentation occurs. How then is class II processing achieved?

The MHC class II α and β chains, as with other membrane glycoproteins, are synthesized in the ER. After synthesis, the $\alpha:\beta$ chain heterodimer engages a type II membrane protein, the MHC class II-associated invariant (Ii) chain—invariant because the Ii gene is nonpolymorphic. The invariant chain forms a trimer complex consisting of three class $\alpha:\beta$ heterodimers and three Ii subunits, with each Ii subunit binding noncovalently to a class $\alpha:\beta$ heterodimer. This interaction of the class II $\alpha:\beta$ heterodimer with Ii serves two important functions. First, a region of Ii binds (with low affinity) to the peptide binding groove/cleft of the nascent class II molecule in the ER, and prevents the loading of peptides transported into the ER from binding to class II in this compartment. Therefore, class II molecules do not bind the same spectrum of peptides as class I molecules, because they do not bind peptides in the ER. Second, Ii targets the class II molecules to the cell's low pH endosomal compartment (rather than the cell surface via the secretory pathway) where protein antigen fragmentation and peptide loading into the class II peptide binding groove occurs.¹⁰⁶

Processing (fragmentation) of protein antigens in the MHC class II pathway is carried out by a variety of acid proteases, and at least one IFN- γ -induced lysosomal thiol reductase (GILT) located in the low pH endosomal compartment. Several related cathepsin cysteine proteases (e.g., cathepsins S, L, B, F), and the unrelated cysteine protease, asparaginendopeptidase (AEP), have been implicated in antigen processing (fragmentation) in endosomes as inhibition of, or deficiency in, one or more of these proteases that can affect the generation of certain antigenic epitopes recognized by CD4⁺ T cells.²⁹⁵

To bind peptides in the endosome, class II molecules must be liberated from Ii. This is achieved by the sequential cleavage of Ii by endosomal proteases (including, AEP, cathepsin S, and cathepsin L), freeing the class II $\alpha:\beta$ heterodimer from the membrane portion of the Ii, and leaving a short fragment of Ii (called *CLIP* for class II-associated invariant chain peptide), which remains bound to the peptide-binding groove of the class II molecule. CLIP must be removed from the class II molecule to make the class II binding groove accessible to peptide fragmentation in the endosome, which is achieved through the action of a MHC-like molecule, DM (HLA-DM for human, H-2M for mouse) and which is encoded in the MHC locus and resides in the endosome. DM catalyzes the dissociation of CLIP from the class II $\alpha:\beta$ heterodimer. As with Tapasin for class I molecules, DM stabilizes the class II molecule as the class II molecule interacts with and sorts through the myriad of antigenic peptides in the endosome, selecting those peptides displaying the correct motif to allow these peptides to stably bind to the class II molecule. This peptide selection process by class II molecules typically occurs in 2 to 4 hours (during the time that the class II molecules reside in the endosome). Once a stable peptide/class II complex forms, DM dissociates; and the complex transits to the cell surface of MHC class II-expressing cells. *Empty* class II molecules (i.e., lacking a peptide in the binding groove) are unstable. Consequently, in the absence of infection

or specific exposure to foreign antigen (e.g., vaccination), it is self-peptides derived from the endosomal proteolysis of cellular proteins (e.g., soluble proteins taken up from the extracellular space by pinocytosis or the residues of phagocytosed apoptotic cell) that are bound to the MHC class II molecules on the surface of uninfected, class II-expressing cells.

Although *de novo* synthesized MHC class II molecules likely play a major role in capturing/presenting processed antigen to CD4⁺ T cells, class II molecules can cycle back into the endosomes from the cell surface, and these *recycled* class II molecules may also capture/present antigenic peptide. Class II molecules containing self-peptides (or less frequently, class II molecules that escape the endosome and exit to the cell surface with CLIP peptide in their groove) appear able to re-enter the endocyte compartment, exchange the bound peptide for a new peptide, and cycle back to the cell surface. By employing this recycling mechanism, MHC class II-expressing cells (in particular, professional APC, as with DC) would increase their chances of capturing and displaying foreign antigenic peptides to CD4⁺ T cells. In immature DCs, endosomal/lysosomal proteolytic activity is weak and newly synthesized MHC class II/Ii complexes are shunted to and retained in the endosome where they will be eventually degraded unless the DC are activated.

ANTIGEN PRESENTATION AND PROFESSIONAL ANTIGEN-PRESENTING CELLS

The hallmark of the adaptive immune system is specificity of foreign antigen recognition. For T cells, this means recognition of antigenic peptides bound to MHC class I or II molecules displayed on the cell surface. The T-cell response proceeds, as we have seen, in two phases. First is the inductive phase: the activation of quiescent primary (or memory) T cells in response to recognition of specialized APC displaying the peptide/MHC complex, resulting in the generation of armed effector T cells. Second is the effector phase, where cells displaying the appropriate peptide/MHC complexes are recognized by the activated T cells. The *classic* class I presentation pathway (which utilizes peptides derived from proteins synthesized *de novo* in the cell) is ideally suited to generate the antigenic peptide/MHC class I complexes recognized by CD8⁺ effectors in response to viral infection of any body cell type. Virus infection of a cell leads to the generation of an ample supply of viral protein substrates for processing by the proteasome. The expression of MHC class I molecules, and the molecular machinery of processing (i.e., the TAP transporter complexes and immunoproteasome subunits) are upregulated by type I and, in particular, type II IFN induced during virus infection by infected cells and by responding NK and effector CD4⁺ T cells (increasing the efficiency of infected cell recognition by CD8⁺ T cells). Furthermore, because antigenic peptide/MHC class I complexes are extremely stable,²⁵⁰ viral peptides bound to MHC class I molecules displayed on the surface infected cells are not transferred to surrounding uninfected cells. Consequently, the resulting destruction of bystander cells by CD8⁺ T cells is negligible. Evidence accumulated over several decades suggests that this classic pathway of cytoplasmic generation of viral peptides and

loading of viral peptides into class I molecules in the ER is employed in the recognition of virus-infected cells by CD8⁺ T cells. As discussed below, many viruses have evolved strategies to disrupt the class I presentation pathway to prevent effector CD8⁺ T-cell recognition of infected cells and sustain virus infection.

Due to the more stringent requirements for the activation of resting naïve T cells, there has been considerable attention given over the last decade to the process of antigen processing and/or presentation by professional APCs (in particular DCs) in the generation of peptide/MHC complexes during the inductive phase of the T-cell response. Although a number of DC subsets had been identified and categorized, as noted above, DC can be conveniently divided into two main subsets: cDC (conventional/myeloid DC) and plasmacytoid (lymphoid) DC (based on the bone marrow progenitor cell types that give rise to these two DC subsets and on the expression of certain DC lineage-specific cell surface molecules.²⁶⁰ The cDCs are the primary APCs, which stimulate antiviral T-cell responses.¹⁷ The DC subset derived from lymphoid progenitors, the plasmacytoid DCs (pDCs), has received considerable scrutiny. pDCs, so called because of their plasma cell-like morphology and surface expression of a CD45 isoform (i.e., the B220 molecule, which, characteristically, is found only in B cells) have weak APC activity but have been demonstrated to be the major source of IFN- α produced early (24 to 48 hours) after inflammatory stimuli, including virus infection.⁴⁹ Therefore, in addition to serving as a potential, albeit weak APC for T cells, the pDCs may serve as a major early innate immune defense against virus infection.⁸⁰

In support of their essential role in immune response induction, DCs (when activated/mature) are 10 to 100 times more potent on a per cell basis as activators of naïve T cells when compared with other immune cell APCs (e.g., macrophages, B cells).² Immature DCs can take up virus by the following several mechanisms:

1. Binding of viruses to their cognate receptors displayed on the DC surface with direct fusion or uptake of bound virus into endosomes, and subsequent release of the viral genome to initiate infection.
2. Phagocytosis of virions using a range of lectin-like, innate immune pathogen pattern recognition receptors displayed by DCs (e.g., DEC 205, DC-SIGN). Although triggering of phagocytosis and the likely engagement of TLR capable of recognizing viral nucleic acids/proteins (i.e., TLR-3, 7, 9) should result in DC activation/maturation, engagement of certain lectin receptors by particular viruses (e.g., HIV interaction with DC SIGN) may induce an inhibitory signal suppressing DC activation.⁷⁹
3. DC uptake of virus nonspecifically by fluid phase macropinocytosis. This bulk uptake of fluid phase soluble and particulate material is a characteristic property of immature DCs.
4. For viruses capable of directly activating the complement cascade (i.e., without prior antibody binding) (e.g., HIV), DCs expressing the complement receptor CR3 (i.e., the integrin complex, CD11b/CD18) can take up (by receptor-mediated endocytosis) virions displaying the activated complement C3 product, iC3b.

Any or all of these uptake mechanisms can directly or indirectly deliver viral polypeptides to the MHC class II and classic class I presentation pathways in DC.

Given the critical role of cDCs in the induction of the T-cell response (in particular, the antiviral CD8⁺ T-cell response,¹⁴⁴ viruses might be expected to have evolved strategies to inhibit the induction of CD8⁺ T-cell responses in virus-infected DCs. As discussed elsewhere in this text, for individual virus genera, evidence indicates that infection of DCs by certain viruses may inhibit the APC capacity of DCs.^{242,253} Furthermore, productive virus infection of tissue DCs at body surfaces could also result in virus dissemination when the DCs traffic to the SLOs. These considerations, as well as the fact that certain viruses with narrow cellular tropism (e.g., papillomavirus), therefore, are not capable of infecting DCs and providing polypeptides for processing via the classic class I pathway, led to the concept of cross-presentation of antigen (including, viral polypeptides) by DCs to CD8⁺ T cells. As discussed above, the likely mechanism(s) of antigen cross-presentation by DCs involves phagocytic uptake by DCs of virus or, more likely, of fragments of productively infected apoptotic cells. Recent evidence points to several potential mechanisms of cross-presentation by DCs, including a mechanism where the DC phagosomes containing viral antigen (taken into the DCs by phagocytosis of virus/virus-infected cellular material) fuses with the ER; therefore, viral polypeptides in this ER/phagosome complex would be available for transport through the Sec61 retrograde transport mechanism into the cytosol for proteasome-dependent proteolysis and subsequent transport of viral peptide into the ER for loading onto nascent MHC class I molecules.¹⁸⁰ Cross-presentation of antigens to naïve T cells is believed to be limited to professional APCs, that is, cDCs and possibly certain macrophage subsets that function at the inductive phase of T-cell responses. The concept of cross-presentation as the mechanism of viral antigen presentation to naïve CD8⁺ T cells, is gaining general acceptance, particularly because it solves several of the nagging issues concerning the induction of CD8⁺ T-cell response to viruses such as papilloma and polio viruses, which presumably do not infect DCs (and to tumor cells that cannot serve as professional APCs). It remains uncertain, however, why most pathogens (e.g., extracellular bacteria, fungi) only trigger CD4⁺ T-cell responses (i.e., do not activate the MHC class I presentation pathway) despite the potential for these antigens to enter the phagocytic compartment of DC.

CYTOKINES AND CHEMOKINES

Many cytokines and chemokines act to orchestrate the innate and adaptive immune responses. The cellular and molecular biology of these molecules have been extensively reviewed.^{175,184} Several of the cytokines also play an important role in T-cell activation and are worth consideration. Interleukin-12 (IL-12) is primarily a product of activated DCs and macrophages, and exists in two forms: IL-12p70 (a heterodimer consisting of the p40 and p35 subunits), and a homodimer of IL-12p40. (The p40 subunit is also part of the heterodimer making up the cytokine IL-23—an important regulator of CD4 Th-17 effector T-cell responses as discussed below.) IL12p70 interacts with its receptor on naïve and activated T cells, providing *signal 3* in the naïve T-cell activation sequence through recruitment and

activation of signal transducers and activators of transcription 4 (STAT-4). The outcome of this signaling process is to promote the differentiation of CD8⁺ T cells into activated cytolytic effector cells, and to help drive the differentiation of CD4⁺ T cells along a pathway leading to effector CD4⁺ T cells capable of secreting IFN- γ on TCR engagement (i.e., the generation of T_H1, T helper 1 effector T cells). The effect of IL-12p70 on T cells is to generate activated effector T cells that are efficient at viral clearance.

IL-2 is a cytokine produced by both CD4⁺ T cells and, to a lesser extent, CD8⁺ T cells, during the initial phase of T-cell activation and differentiation.¹³² Engagement of the high affinity IL-2 receptor (expressed only after T-cell activation) by IL-2 drives T-cell proliferative expansion. Although IL-2 was initially believed to be the primary T-cell growth factor (acting in an autocrine fashion to stimulate T-cell proliferation), T-cell activation and proliferative expansion occur normally in the absence of IL-2 (e.g., in IL-2-deficient patients or experimental animals with a targeted disruption of the IL-2 gene). Therefore, it appears that, in the absence of IL-2, other cytokines (e.g., IL-15) can support the normal T-cell expansion in response to antigenic stimulation. As with many cytokines, IL-15 can be produced by a variety of cell types, both constitutively and in response to inflammation. A genetic deficiency in IL-2 results not in a defective T-cell response to antigen, but rather paradoxically, in exaggerated T-cell proliferation (lymphoproliferative disease) and the development of autoimmune responses caused by the defective generation of regulatory T cells.²³⁷ Recently, IL-2 produced by effector CD4⁺ T cells has been shown to regulate the production by CD8⁺ T effector cells of the regulatory cytokine IL-10 during respiratory virus infection.¹²³

Other cytokines, for example, IFN- γ , IL-4, IL-6, and transforming growth factor β (TGF- β) are, like IL-12, sources of *signal 3* and therefore are important regulators of the adaptive immune system and immune cell function during the adaptive immune response to virus infection. IFN- γ is the product of a single gene with minimal allelic variation in the coding sequence of the gene. It is produced during virus infection primarily by activated CD4⁺ T cell and CD8⁺ T cells (and some NK T cells) in response to TCR engagement and by NK cells after engagement of stimulatory NK cell receptors. The role of IFN- γ in augmenting antigen presentation (i.e., upregulation of MHC class I and II expression, immunoproteasome subunit induction) has been discussed earlier. IFN- γ also plays a critical role in activating mononuclear phagocytes (macrophages) to destroy infected intracellular bacteria, and it presumably plays a similar role in the destruction of virus and, possibly, virus-infected cells when armed effector T cells respond to viral antigen at peripheral sites of virus infection. The early production of IFN- γ (likely produced by NK cells entering the SLO in response to infection) during the initiation of T-cell responses to antigen can drive T-cell differentiation to a type 1 (T_H1) pathway (characteristic of antiviral T-cell responses). The IFN- γ gene is rendered transcriptionally active by exposure of responding primary T cells to IL-12p70, resulting in IFN- γ production by activated effector T cells on subsequent TCR engagement by antigen.¹⁹³ IFN- γ signaling through its receptor is mediated primarily by STAT-1.

Interleukin-4 is produced at high levels by activated CD4⁺ T cells that have differentiated along the type 2 (T_H2) pathway.¹⁹³

IL-4 may also be produced at low levels in primary T cells early in the response to antigen and by NK T cells and NK cells. Exposure of responding CD4⁺ T cells to IL-4 early in the activation/differentiation sequence is essential for the generation of T_H2 effector T cells in the SLO. The early low-level production of IL-4 by activated T cells (or by NK T cells and NK cells recruited to the SLO) before their commitment to T_H1 or T_H2 differentiation may be sufficient to render the IL-4 gene locus capable of high-level IL-4 production by CD4⁺ T_H2 effectors on TCR engagement.²⁸³ The NK T-cell subset, which rapidly produces high levels of IL-4 early in the response to pathogens, has been suggested to be a potential source of IL-4, which can regulate conventional $\alpha\beta$:TCR T-cell differentiation in the SLO in response to antigen. IL-4 produced by activated T cells serves both as a B-cell growth-promoting factor and also triggers immunoglobulin type switching during B-cell activation/differentiation. Engagement of the IL-4 receptor activates STAT-6 to mediate the effect of IL-4 on responding B and T cells. As will be discussed, IL-4 and IFN- γ act antagonistically to regulate T-cell differentiation and T-cell effector generation into T_H1 or T_H2 effectors.

The cytokines IL-6 and TGF- β play a critical role in driving naïve CD4 T-cell differentiation into IL-17-producing effector T cells, and in the case of TGF- β , an essential role in the development of T regulatory cells. IL-6 is a proinflammatory cytokine, the expression of which is upregulated following an inflammatory stimulus such as virus infection, and signaling through the IL-6 receptor is mediated by STAT-3. TGF- β exists on cell surfaces in an inactive form and its expression is regulated at the level of transcription, translation, and posttranslational modifications.²⁴⁵ Signaling through of the TGF- β receptor is signal transducing mothers against decapentaplegic protein (SMAD) dependent. Both cytokines can be produced by hematopoietic and nonhematopoietic origin cells. Production of IL-6 and TGF- β in the SLO at the time of infection will trigger naïve CD4⁺ T-cells to differentiate into T_H17 T_E as discussed below (see text under heading “CD4⁺ T_E Effector Mechanisms”).

EFFECTOR ACTIVITIES OF B CELLS

The antiviral activities of B cells are largely mediated by antibodies,^{32,72,91,139,305,325} although B cells may also have modulating effects on innate immunity. Antibodies are distinguished from T-cell effectors in that they have activity against free virus particles as well as against virally infected cells. They are the first line of defense against viral infection. In a very real sense, the adaptive antiviral activities of antibodies and T cells are complementary and should be considered together in attempting to understand immune responses to viruses.⁸ Nevertheless, it is revealing to consider the antiviral activities of antibodies at different layers of complexity³²: *in vitro*, *in vivo* in the absence of other adaptive immune effectors as revealed by passive antibody transfer studies; and *in vivo* in the presence of T-cell responses as in natural infection or following some vaccination strategies.

ANTIVIRAL ACTIVITIES OF ANTIBODY *IN VITRO*

As stated earlier, antibody can act against both free virus and infected cells. This is presented schematically in Figure 9.4 for an enveloped virus. Probably the most studied antiviral activ-

ity of antibody *in vitro* and the one most important for antibody protection *in vivo* is neutralization of free virus particles. Neutralization has been defined as the loss of infectivity that ensues when antibody molecule(s) bind to a virus particle, and usually occurs without the involvement of any other agency. As such, this is an unusual activity of antibody paralleled only by the inhibition of toxins and enzymes.⁶⁷ The mechanism(s) of neutralization have been much debated over the years. The simplest models are based on steric obstruction of virus attachment or virus entry by the antibody molecule.^{116,145,215,269} The relatively large bulk of the antibody molecule, very roughly similar to that of a typical viral spike for an enveloped virus, is suggested to be critical. Such models predict that the neutralizing efficacy of an antibody should be related primarily to its affinity for antigen on the virion surface, and the precise epitope recognized should be of lesser, but potentially significant, importance. Indeed, clear evidence exists that antibodies can neutralize viruses without binding directly to functional sites on the virion surface.^{22,228} The models described can be very loosely termed occupancy or coating models, where the degree of coating of the virus surface by antibody to achieve neutralization differs between models. One model noted a striking linear relationship between the surface area of a set of viruses and the number of antibody molecules bound to virus at neutralization.²¹² This implied that, for these viruses at least, a coating density corresponding to about half the available antibody sites occupied on the virus produced neutralization. This model is likely to be less applicable to complex viruses expressing multiple surface proteins (e.g., the herpes or pox viruses). A related model of neutralization of flaviviruses proposes that highly accessible epitopes may require lower occupancy than poorly accessible epitopes to reach a threshold for neutralization.²²⁰ Further models taking into account kinetic factors in virus neutralization are being developed.

Alternative neutralization models suggest that (a) viruses are neutralized by the binding of one or only a few antibody molecules to critical sites on the virion surface; (b) conformational changes in envelope or capsid molecules are crucial to neutralization; and (c) viral inactivation by antibody can occur following entry to infected cells, for example, by blocking virus uncoating⁶⁷ or by interaction of the Fc of IgG with TRIM21.^{169a} Considerable debate remains in the area of antibody neutralization mechanism and, furthermore, it may be that different mechanisms are operative for different viruses under differing conditions.

Antibody activity against free virus particles can be augmented by Fc-mediated effector systems in several ways. First, complement activation²⁷¹ by virion-bound antibody and deposition of complement components on the virion surface can enhance neutralization.¹⁸³ Occupancy/coating models argue that this reflects an increased coating of molecules on the virion that hinders productive interaction of virion and target cell. Second, complement activation can lead directly to virolysis by deposition of the terminal components of complement in the viral membrane. Third, Fc and complement receptors can bind antibody or complement-coated virions, leading to phagocytosis followed by inactivation in an intracellular compartment within the phagocyte. This process has been described *in vitro* for the picornavirus foot-and-mouth disease virus (FMDV) and is believed to be important *in vivo* in protection against FMDV.¹⁸¹ It is likely that neutralizing antibodies, which tend

FIGURE 9.4. Antibody activities against free virus particles and virally infected cells. A: Activities against free virus particles. The primary activity is probably neutralization, whereby antibody molecules bind to virion surface proteins and block infection. Virion-bound antibody molecules may also trigger lysis of virions via complement or phagocytosis of virions. An enveloped virus expressing only one surface protein is shown. A virus expressing multiple surface proteins (e.g., a herpes or poxvirus) may not be neutralized by antibody saturation of a single surface protein. Non-functional surface molecules may also be present on infectious virions for some viruses such as HIV.²²⁴ Nonneutralizing antibodies may bind to such molecules and trigger the elimination of infectious virions by effector systems or perhaps trap virus *in vivo* and prevent contact with target cells. **B:** Activities against virally infected cells. Neutralizing antibodies will bind to the proteins that are also expressed on virions (typically Env proteins). Nonneutralizing antibodies will bind to proteins that are expressed on infected cells but not virions (e.g., NS1 protein of dengue virus) or that are also expressed on virions but whose blockade does not lead to neutralization (e.g., neuraminidase on influenza virions). (Reproduced from Burton DR. Antibodies, viruses and vaccines. *Nat Rev Immunol* 2002;2:706–713, with permission.)

to coat the viral surface, will be most effective in triggering virolysis or phagocytosis. An antigen present at relatively low density on the surface of a virion could, however in principle, bind antibody without mediating neutralization. Such non-neutralizing antibody could nevertheless trigger virolysis or phagocytosis.

Antibodies can act, not only against free virions, but also against infected cells by binding to viral proteins expressed on the surface of virally infected cells (Fig. 9.4). Fc-mediated effector systems can lead to cell lysis or clearance via complement-dependent cytotoxicity (CDC) or antibody-dependent

cellular cytotoxicity (ADCC). In the case of CDC, activation of the classic pathway by antibody that complexes arrayed viral proteins on the infected cell surface can lead to C3b deposition and uptake by effector cells or the deposition of the terminal complement components in the infected cell membrane resulting in lysis.¹⁸ For ADCC, the antibody array on the infected cell surface is recognized by Fc receptors on effector cells, triggering killing of the infected cells. Antibody can also inhibit (a) virus release from infected cells⁹¹ by simply binding to viral proteins at the infected cell surface and (b) cell-to-cell transmission of virus^{30,211} by mechanisms that are thought to be very

similar to those that lead to virus neutralization. Binding of antibody to the infected cell surface, particularly of neurons, has also been suggested to inhibit viral replication inside cells, presumably via signaling mechanisms.^{87,160}

Generally, it appears that antibody is less effective against infected cells than against free virions. For instance, higher concentrations of neutralizing antibody are required to inhibit cell-to-cell transmission than are required to inhibit infection by free virions.^{119,211} Similarly, a higher concentration of antibody has been associated with effective CDC and ADCC than has neutralization.¹¹⁷ It is expected that neutralizing antibodies will be effective against infected cells if they bind to envelope molecule presentations on free infected cells that are also expressed on virions. Antibodies that bind to molecules expressed on infected cells but not virions, for example, the NS1 protein of dengue virus,¹¹⁴ can be effective against infected cells, although they are nonneutralizing.

Polymeric IgA and IgM have been shown to be capable of intracellular neutralization of virus. These antibodies are actively transported over the mucosal epithelium after binding to the polymeric immunoglobulin receptor and may, during transport, contact and neutralize transcytosing viruses.^{25,88,139,178}

Finally, antibody can enhance viral infection *in vitro* under certain circumstances, generally in the presence of subneutralizing concentrations of neutralizing antibodies. Enhancement is mediated by Fc receptors in some cases (e.g., dengue virus),^{16,104,109,191} but not in other cases where enhancement is observed with antibody Fab fragments.²⁷⁷ The occupancy model of neutralization described above explains enhancement of infection as an effect that occurs at low occupancy of virion sites in the presence of permissive cells (e.g., those bearing Fc receptors). As antibody concentrations increase, coating of the virus increases, eventually resulting in neutralization.

ANTIVIRAL ACTIVITIES OF ANTIBODY *IN VIVO*

The classic approach to determine the protective activities of antibody *in vivo* is to passively transfer immune sera or monoclonal antibodies to a naïve animal, challenge with virus, and observe the outcome. This approach has consistently shown—for many different viruses, animal models, and challenge routes—a good correlation between the protection achieved and antibody serum neutralizing activity measured *in vitro*.²¹² It should be noted that this does not necessarily mean that neutralization is the mechanism of protective activity. Neutralizing antibodies are probably those that bind most effectively to free virions and to virus-infected cells (at least for many enveloped viruses) so that, in principle at least, any of the mechanisms of antiviral activity presented in Figure 9.4 could be operative in protection.

Generally speaking, protection in animal models is achieved when neutralizing titers in the serum of the animal at the time of virus challenge are relatively high, often of the order of 1:100 or higher. In other words, the serum of the animal can be diluted 100-fold and 50% to 90% (depending on the study and assay) neutralization achieved *in vitro*. In some instances, protection can be described as sterilizing in that no evidence is seen of viral replication following challenge. Serum neutralizing titers (80%) of 1:380 or greater provide sterilizing immunity in the lungs of cotton rats challenged with respira-

tory syncytial virus (RSV),²²⁵ and titers as high as 1:400 (90%) and 1:38 (~100%) or as low as 1:1 (90%) provide sterilizing immunity against challenge of macaques with chimeric simian-human immunodeficiency virus (SHIV)^{115,198,214} In other instances, such as challenge with lymphocytic choriomeningitis virus (LCMV) in a mouse model³¹² and with Ebola virus in a guinea pig model,²¹³ high titers of neutralizing antibody do not provide sterilizing immunity but do prevent disease. In the latter case, similar titers prevent disease due to Ebola virus in guinea pigs but have no effect on disease course in macaques.²⁰⁵ However, more recently, a cocktail of neutralizing antibodies has been shown to protect macaques against disease due to Ebola virus infection.^{225a} In most instances, however, it has not been established whether sterilizing immunity has been achieved.

A number of possible explanations exist for the neutralizing titers required for protection in many animal studies. If the assumption is that neutralization is the dominant protective mechanism, then for some viruses/animal models/challenge routes it may be necessary for protection for antibody to mop up essentially every last virus particle requiring an excess of antibody. With the same assumption, the protective activity may be achieved at a tissue site with a lower antibody concentration than that of serum, again leading to an apparent overcapacity. Alternatively, protection may require an additional activity of neutralizing antibody distinct from neutralization. For instance, it may be that activity against infected cells, as well as (or in some cases even instead of) activity against free virions, is needed to provide protection. This would be consistent with observations that antibody concentrations required for activities against infected cells (e.g., blocking cell-to-cell transmission) are typically higher than required for neutralization of free virus particles. A further alternative explanation is that the neutralization *in vitro* is not reflective of the process *in vivo*, for example the target cell type used *in vitro* may have important differences from the target cell *in vivo*.

Animal model studies do provide evidence that mechanisms other than neutralization can be important in protection by neutralizing antibodies. In some cases, protection is found to be as effective with F(ab')₂ fragments, which lack the Fc domain and, therefore, are unable to trigger effector functions, as the corresponding whole IgG molecule. In other cases, however, F(ab')₂ fragments that are equally active as whole IgG molecules at neutralization *in vitro* are ineffective at protection. For yellow fever virus,²⁴³ it has been shown that neutralizing mouse IgG1 antibodies (poor activators of effector functions) are ineffective at protection, whereas IgG2a molecules (good activators) of the same specificity are effective. Similarly for vaccinia virus,¹⁸ it has been shown that human IgG1 but not IgG4 isotypes of human mAbs are effective. In many of the examples in mouse models in which the Fc part of IgG is important, protection is independent of complement.²¹² This implies that protection by neutralizing antibodies in these cases may require activity against infected cells and involves ADCC or phagocytosis. Many examples of protective activity due to passively transferred nonneutralizing antibodies have been described. The activity appears to be directed at infected cells (Fig. 9.4) and generally appears to be somewhat less potent than that due to neutralizing antibodies. For instance, a number of cases have been reported where neutralizing antibodies are protective against higher challenge doses or more pathogenic viruses

than nonneutralizing antibodies. In many cases, protection by nonneutralizing antibodies is shown to depend critically on the Fc part of the antibody molecule and to occur in complement-deficient mice, suggesting that ADCC (or phagocytosis) may be crucial in clearing antibody-complexed infected cells. Protection with nonneutralizing antibodies is mostly restricted to those antibodies directed against enveloped viruses.

Passive transfer of antibodies to humans has been shown to provide protection against disease caused by a number of viruses, including hepatitis B, hepatitis A, measles, polio, and RSV.³⁹ Indeed, a humanized, neutralizing anti-RSV monoclonal antibody is in clinical use to protect at-risk infants.¹⁰¹ In some or many of these cases, it is unlikely that the titers of passively transferred neutralizing antibody achieve the levels necessary to offer sterilizing immunity, although this has not been widely studied. Rather, it would seem that neutralizing antibody sufficiently blunts the infection to allow the development of other protective mechanisms, presumably a CD8⁺ T-cell response, active antibody responses, and innate immunity (see below). The protection of young infants by maternal neutralizing antibodies likely falls into this category. Maternal antibodies may “attenuate infection during the initial months of life, thereby creating optimal conditions for the natural immunization of the child as a result of infection”.³²³ In some instances (e.g., rabies virus infection), passive antibody has been shown to protect against disease after exposure, when some measure of infection is clearly established. Once infection is clearly established, however, reports of beneficial effects of passive antibody are limited.

Many important human viral pathogens gain entry to the host via mucosal surfaces. Passive transfer studies show that antibodies present in the mucosal compartments at the time of exposure can protect against viral challenge.^{139,202} Both mucosal secretory IgA (sIgA) and systemic IgG have been shown to be effective. Dramatically, classically nonneutralizing IgA can protect against rotavirus challenge in mice by an intracellular “neutralization” mechanism.³¹ A recent study elegantly shows how different antibody specificities can interfere with HPV infection *in vivo* in a cervicovaginal mouse model at two stages: first to prevent virion binding to the basement membrane and second to prevent virion association with the epithelial cell surface.⁶²

Evidence for the importance of antibody enhancement of viral infection *in vivo* is limited.²⁷⁷ Early observations on dengue virus infection in humans¹⁴⁶ are the most convincing, and the case for antibody enhancement leading to dengue-associated disease has been strengthened by recent observations in animal models.^{13,321}

In terms of human vaccination, it is often stated that neutralizing antibodies are the best correlate of protection.^{7,222} This is not to argue that neutralizing antibodies are the sole or even necessarily the most important mechanism of protection, although the circumstantial evidence in many cases is quite strong. For smallpox, neutralizing titers of 1:20 to 1:32 indicate protective immunity.¹⁰⁵ For measles, low titers of neutralizing antibody (<120 mIU/ml) are strongly associated with clinical disease, intermediate titers (~200 to 900) are associated with a substantial proportion of subclinical infections reflected in boosting of antibody titers following exposure and high titers (>~1,000) with no indication of subclinical infection and possible sterilizing immunity.

EFFECTOR ACTIVITIES OF T CELLS

The categorization of $\alpha:\beta$ TCR T cells into CD8⁺ and CD4⁺ subsets not only demarcates the MHC molecules that restrict recognition (i.e., class I or class II), but also has functional significance at the effector level (Table 9.5). CD8⁺ T-cell effector cells (CD8⁺ T_E) are capable of destroying antigen-displaying cells (e.g., virus-infected cells expressing the appropriate peptide/MHC class I complex) by direct cell-to-cell contact. CD8⁺ T_E also produce/secrete several cytokines with antiviral activity (e.g., IFN- γ , TNF- α) on TCR engagement. CD4⁺ T-cell effectors (CD4⁺ T_E) primarily function by release of cytokines (notably, IFN- γ , and/or IL-4, IL-5) in response to antigenic stimulation. CD4⁺ T_E, however, in rare instances, can also acquire killing capacity by direct contact with cells displaying the appropriate peptide/MHC class II ligand recognized by the TCR/CD4 complex. The differentiation of the naïve T cells into T_E, in particular naïve CD4⁺ T-cell differentiation into T_H1, T_H2, or T_H17 effector cells, is regulated by a variety of factors (as discussed below).

TABLE 9.5 Effector Activation of Activated CD8⁺ and CD4⁺ T Cells

Effector type	Target cell	Effector mechanism
CD8 ⁺ T cell	MHC class I ⁺	–Direct cytolysis (cell–cell contact) –Granule exocytosis (perforin/granzyme) –FasL (T cell) – Fas (infected target cell) interaction Cytokine synthesis –IFN- γ , TNF- α , chemokines
CD4 ⁺ T-cell – T _H 1	MHC class II ⁺	Cytokine synthesis –IFN- γ , TNF- α , chemokines
CD4 ⁺ T-cell – T _H 2	MHC class II ⁺	Cytokine synthesis –IL-4, IL-5, IL-13
CD4 ⁺ T-cell – T _H 17	MHC class II ⁺	Cytokine synthesis –IL-17A/F, IL-6, +/-IL-21

MHC, major histocompatibility complex; IFN, interferon; TNF, tumor necrosis factor.

CD8⁺ T_E EFFECTOR MECHANISMS

The CD8⁺ T_E destroy *target* cells (e.g., virus-infected cells) following direct cell-to-cell contact, by two distinct mechanisms. One mechanism is by granule exocytosis.¹⁶¹ Mature (fully differentiated) CD8⁺ T_E contain lytic granules within their cytoplasm, and TCR engagement on the T_E by peptide/MHC class I complexes on the target cell results in the formation of intermolecular signaling clusters (consisting of TCR α : β , CD3, and integrins, e.g., LFA-1). In response to TCR engagement, and signal transduction, the cytoplasmic granules are directed by the cellular microtubule-organizing center along actin filaments to the site of TCR aggregation where the granules are then released onto the surface of the target cell. The adhesive interaction between the T_E and the target cell is stabilized/strengthened through the interaction of LFA-1 (on T_E) with its ligand, ICAM-1 (on the target cell). The lytic granules contain a protein, perforin, which has a sequence homology to the complement component C9. The granules also contain a set of serine proteases, known as *granzymes* (for granule enzymes), which are present in a proenzyme form within the T_E granule as part of a multimeric complex with perforin imbedded within a scaffold consisting of proteoglycan, serglycin, which are activated (by granule-associated cathepsin C) on granule exocytosis. Because of its homology to C9, the perforin monomer released onto the target cell was believed to intercalate and polymerize (in the presence of extracellular Ca²⁺), forming a pore within the target cell plasma membrane that allows the granzymes access to the target cell cytoplasm. More recent evidence suggests that released granzymes bind directly to target cells, possibly through cell surface receptors, and either gain direct access to the cell cytoplasm or are first internalized into endosomes.²⁸ Perforin may act by facilitating the transfer of granzymes from the cell surface or endosome into the cytoplasm. The granzyme family of serine proteases consists of at least five members in the human (granzyme A, B, C).²³⁵ They are believed to function by activating cell death pathways in the target cells, including both direct activation of the caspase-dependent cell death mechanism, and the caspase-independent mitochondrial death pathway associated with granzyme-dependent activation of proapoptotic Bcl-2 family members (e.g., BID, BAX).¹⁰ Although the mechanism of action and function of each granzyme is not completely understood at present, at least one granzyme, granzyme B, is present in both CD8⁺ T_E and NK cell lytic granules, and acts by proteolytic cleavage and activation of procaspases (procaspase 3 caspase 3) and proapoptotic Bcl2 family members (e.g., BID \rightarrow BID*) resulting in the indicative DNA fragmentation and mitochondrial damage characteristic of apoptosis. An additional granule-associated lytic molecule, granulysin (present in human T_E), can form pores in membranes and may play a role in the destruction of certain bacteria by direct lysis.¹⁵¹

The CD8⁺ T_E can also destroy target cells by the upregulation (in response to TCR engagement) of the TNF family protein, CD154 (FasL, CD95L) on the T_E, and engagement of its receptor, the TNF receptor family member, CD95 (Fas), on the infected target cell.⁶⁵ CD95 engagement results in the recruitment/activation of caspases and apoptotic death of target cells. Studies in experimental models of virus infection suggest that both the Fas/FasL and the granule exocytosis mechanisms can contribute to the elimination of virus-infected cells, and virus

clearance by CD8⁺ T_E.^{28,286} The relative contribution of each lytic mechanism to virus clearance differs for different viruses.

The CD8⁺ T_E also produce a number of cytokines in response to TCR engagement by antigen, most notably IFN- γ and TNF- α . The production/secretion of these effector cytokines appears to be tightly regulated and typically requires TCR-dependent signaling in the CD8⁺ T_E.²⁶⁸ IFN- γ exhibits its antiviral effects through upregulation of MHC molecule expression and stimulation of the MHC class I processing/presentation pathway in infected cells. Because IFN- γ is a potent activator of tissue macrophages, activated macrophages would also have the capacity to take up and destroy virus/virus-infected cells. TNF- α , as can the other member of the TNF ligand family, CD154 (FasL), induces apoptosis of infected cells expressing the receptor for TNF α , and in addition can signal the production of proinflammatory/anti-viral cytokines through receptor-dependent NF- κ B activation. In addition, recent evidence has emerged from the analysis of experimental models of acute virus infection that CD8⁺ T_E responding to infection can serve as a major source of the regulatory cytokine IL-10.²⁷⁸ This T-cell derived IL-10 may act to attenuate excess inflammation associated with T cell-dependent virus clearance mechanisms.²⁷⁸

CD4⁺ T_E EFFECTOR MECHANISMS

An essential role of activated CD4⁺ T cells in antiviral immunity is to provide *help* for responding B cells in the SLOs in the production of anti-viral antibody. Emerging evidence suggests that CD4⁺ T cells (presumable CD4⁺ T_E effectors) also play a role, not yet completely defined, in the development and maintenance of the memory CD8⁺ T-cell response during virus infection.^{264,304} CD4⁺ T_E express effector activity through the release of cytokines on TCR engagement (i.e., recognition of specific peptide/MHC class II complexes on target cells). CD4⁺ T_E had originally been categorized as T_H1 (type 1 or T helper 1) or T_H2 (type 2 or T helper 2) T_E, based on the constellation of cytokines produced. More recently a third major CD4⁺ effector T-cell subset or lineage has been identified, the T_H17 CD4⁺ T_E. Among these CD4⁺ T-cell subsets, the T_H1 CD4⁺ T_E, which produce IFN- γ and to a lesser extent TNF, serve the most prominent role as the critical CD4⁺ T_E in virus infection. The hallmark of T_H1-induced inflammation is accumulation of mononuclear cells (inflammatory macrophages, monocytes, DCs, lymphocytes, etc.) at sites of infection. The IL-4, IL-5, IL-13 producing T_H2 CD4⁺ T cells are recognized as a major T_E responding to helminth (worm) and certain parasitic infections, and they play a pivotal role in orchestrating the allergic responses to nonpathogenic environmental antigens. The response of T_H2 T_E is characterized by the development of IgE antibody to antigens and an inflammatory response rich in eosinophils.³⁰⁷

As their name implies, the T_H17 T_E produce IL-17A/F (as well as IL-6 and in some instances IL-21). T_H17 T_E release these cytokines at sites of infection following TCR engagement by antigen. Because of the ability of these cytokines, in particular IL-17, to activate epithelial cells to produce chemokines that are chemotactic for neutrophils, T_H17 T_E are potent inducers of neutrophil recruitment to sites of infection. In keeping with the neutrophil-rich inflammatory response induced by these

T_E , they have been implicated as important adaptive immune effectors in the host response to extracellular bacteria and fungi, as well as in the pathogenesis of certain autoimmune diseases previously believed to be orchestrated by T_H1 T_E . The contribution of T_H17 T_E to the adaptive immune response to the virus infection has yet to be firmly established—although, not surprisingly, T_H17 responses have been reported to be dysregulated in HIV-infected patients,¹⁹² and in one model of experimental virus infection in the CNS, the development of a T_H17 T_E response has been reported to suppress the expression of $CD8^+$ T-cell effector activity.⁹⁸

The strict classification of $CD4^+$ T_E responses into T_H1 , T_H2 , or T_H17 categories is somewhat artificial and based largely on *in vitro* studies where differentiation of naïve $CD4^+$ T cells into one of these $CD4^+$ effector cell subsets can be skewed to produce a single T_E subset exclusively. During the course of antigen exposure/infection *in vivo*, $CD4^+$ T_E capable of producing both the T_H1 and T_H2 cytokines (or T_H1 and T_H17 cytokines) are generated; and it is the relative proportion of the T_H1 (IFN- γ , TNF- α) or T_H2 (IL-4, IL-5) or T_H17 (IL-17, IL-6) T_E subsets in the T cells responding to infection that dictates the overall balance of the $CD4^+$ T_E response. As noted, it is the milieu in which $CD4^+$ T cells activate or differentiate in response to antigen in the SLOs that dictates the balance between T_H1 , T_H2 , or T_H17 $CD4^+$ T_E generation.⁵⁰ Numerous factors control the $CD4^+$ T-cell differentiation program, and the relative proportion of T_H1 or T_H2 T_E generated. Among these factors are (a) the form and dose of antigen/pathogen; (b) the APC response (in particular, DC) that express cell surface molecules after antigen encounter that can influence $CD4^+$ T-cell differentiation; and (c) cytokine production by APCs (e.g., IL-12p70) and by innate immune cells present in the SLO (e.g., IFN- γ from NK cells, IL-4 from NK T cells, and IL-6 and TGF- β from mononuclear phagocytes and stromal cells). Detailed discussion of the contribution of these $T_H1/T_H2/T_H17$ differentiation influences is beyond the scope of this chapter but has been reviewed by others.^{50,270} Whereas virus infection, in general, drives $CD4^+$ T-cell differentiation toward the development of T_H1 $CD4^+$ T_E responses, evidence indicates that, in certain chronic human infections, T_H2 $CD4^+$ T_E responses may predominate.^{34,270} Because the induction of the T_H2 $CD4^+$ T_E response with IL-4 (and IL-10) production can suppress the development of a T_H1 $CD4^+$ T_E response characteristic of the adaptive immune response to virus infection, this form of virus-induced immune deviation could potentially result in the inhibition of virus clearance, leading to the development of persistent infection. Although virus infection typically results in the development of $CD8^+$ T_E , which are *T_H1 -like* (i.e., producing IFN- γ , TNF- α), differentiating $CD8^+$ T cells may also be deviated toward the T_H2 effector response (i.e., weakly cytolytic T_E producing IL-4, IL-5), potentially resulting in decreased virus clearance efficiency by these antiviral T_E .³¹⁰

Whether two other recognized subsets of $CD4^+$ T lymphocytes, the recently appreciated T follicular helper (T_{FH}) T cells and T_{reg} cells can be classified as T_E is up for debate and may simply be a matter of semantics, that is, how one defines an “effector” cell. The factors controlling the differentiation of naïve $CD4^+$ T cells into these various activated T-cell subsets as well as their cytokine profile and role in adaptive immune responses are summarized in Table 9.5. The properties of T_{reg} cells and their role in virus infection are discussed in the next section.

REGULATORY T-CELL FUNCTION IN ANTI-VIRAL ADAPTIVE IMMUNE RESPONSES

T_{reg} cells are a subset of $CD4^+$ T cells that express the FoxP3 lineage commitment transcription factor and are crucial for maintaining self-tolerance in the periphery.^{81,236} Despite the fact that CD25 and FoxP3 expression are reliable markers for T_{reg} cells in mice, both FoxP3 and CD25 are also expressed by activated T cells in humans. Therefore, FoxP3 expression alone does not serve a reliable T_{reg} marker. Recently additional markers, such as CTLA-4 and lymphocyte activation gene-3 associated protein (LAP), have been identified as human T_{reg} markers: CTLA-4 is known to be functionally active for T_{reg} cells⁸⁴ and LAP (a TGF- β binding protein) surface expression is enhanced on functional human T_{reg} .²⁸⁷ In addition, although lower expression of CD127 has been correlated with FoxP3 expression and suppression in humans,¹⁶⁴ activation of T_{reg} is recently shown to result in an increase in CD127 expression.²⁶² Nevertheless, a combination of these markers can allow for improved identification of T_{reg} in humans.

The various regulatory T cells are categorized as (a) naturally occurring, thymus-derived $CD4^+CD25^+$ T cells (named as $CD4^+CD25^+T_{reg}$)^{122,207}; or (b) induced, peripheral T cells, which include $CD4^+CD25^-$ T cells, T_H3 cells, and $CD8^+$ T cells.⁵⁵ T_{reg} subsets are defined by differences in their cell surface marker expression, their cytokine secretion patterns, and their mode of suppression. There is evidence of the generation of FoxP3⁺ suppressive cells from FoxP3⁻ nonsuppressive cells both *in vivo* and *in vitro*. These cells are referred to as inducible T_{reg} , adaptive T_{reg} , or iT_{reg} . The factors involved in *in vivo* conversion are not precisely defined. However, TCR activation in the presence of TGF- β has successfully induced T_{reg} development *in vitro*. Two other types of peripherally induced regulatory cells are named Tr1 and Th3. Tr1 causes immunosuppression by secretion of large amounts of IL-10; whereas Tr1 cells develop in the presence of IL-10, IL-15 promotes the survival of these cells. Tr1 cells have regulatory function, but do not express FoxP3. Th3 cells are developed in the presence of TGF- β and also produce a large quantity of this cytokine. Importantly, T_{reg} activity can be modulated by exposure to costimulatory molecules. For instance, activation of OX40 and 4-1BB on $CD4^+CD25^+$ T_{reg} results in increased proliferation; and stimulation of 4-1BB has also been implicated in the maintenance of suppressive function.

T_{reg} cells play a critical role in the regulation of immune responses to viral infection as well as the prevention of tissue damage caused by viral infection. Particularly, T_{reg} cells are involved in suppressing effector T cells in chronic viral infections such as HSV, Epstein-Barr virus (EBV), and HCV, having the appearance of $CD4^+$ regulatory T cells in chronic viral infection. In case of HCV infection, the frequency of $CD4^+CD25^+$ regulatory T cells in chronic patients is greater than those in recovered or healthy patients,^{24,33,276} suggesting that natural T_{reg} s are associated with the establishment of HCV persistent infection. Apparently, the suppressor function of $CD4^+CD25^+$ T cells derived from chronic HCV patients does not rely on soluble mediator(s) (i.e., cytokines) because neutralizing antibodies to either IL-10 or TGF- β do not reverse suppression.²⁴ In addition, the frequency of $CD4^+CD25^{hi}$ T cells in patients with hepatocellular carcinoma is greater than in individuals who are chronically infected with HCV.²⁰⁴

Besides the role of regulatory T cells in suppression of host immune responses to viral infection, T_{reg} cells are paradoxically

essential to control tissue damage caused by host immune responses to viral infection. Direct evidence of a role for regulatory T cells in preventing immunopathology has come from studies using murine models of viral infection. Theiler's murine encephalomyelitis virus (TMEV) infection induces CD4⁺ T cell-mediated demyelinating disease¹¹⁰ such that TMEV-specific CD4⁺ T cells transferred into susceptible, irradiated C/cByJ mice accelerate clinical disease and enhance TMEV-specific delayed-type hypersensitivity (DTH). Importantly, CD8⁺ T cells from infected C/cByJ mice suppress the *in vivo* disease progression as well as virus-specific T-cell responsiveness in recipients of TMEV-specific CD4⁺ T-cell blasts. So, the transfer of virus-specific CD8⁺ regulatory T cells at the time of Theiler's virus infection reduced tissue damage by preventing the pathogenic role of CD4⁺ T cells. In case of HSV infection, depletion of CD4⁺CD25⁺ T cells before viral infection increases the generation of virus-specific CD8⁺ T-cell responses and viral clearance.^{280,281} In contrast, the severity of T cell-mediated lesions in the cornea of HSV-infected mice was increased upon removal of CD4⁺CD25⁺ T cells. Therefore, CD4⁺CD25⁺ T_{reg} cells are likely involved in reducing the severity of immune-mediated inflammatory lesions by preventing the pathogenic effects of CD4⁺ T_{H1} cells as well as limiting the migration of these cells to inflammatory sites. During chronic viral infections, T_{reg} cells might be beneficial to the host by maintaining a balance between efficient effectors and memory responses, but with a low level of inflammation to limit host tissue damage.

Numerous mechanisms are utilized by eliciting suppressive function of T_{reg} cells. One way is through the production of the suppressive cytokines such as TGF- β and IL-10. Although most studies indicate that the suppressive effect of T_{reg} cells is not mediated by soluble factors,²⁵⁷ that does not exclude the possibility of contribution of cytokines acting in proximity or cell-bound cytokines. In fact, TGF- β blockade appears to reduce the suppressive function of T_{reg} cells following the administration of high amounts of TGF- β antibodies,¹⁹⁴ and T_{reg} production of IL-10 is also necessary for protection in a murine colitis model.²⁷⁹ Another way for suppressive function of T_{reg} is mediated by cell surface molecule such as CTLA-4 to negatively regulate T-cell activity and proliferation. The importance of CTLA-4 to T_{reg} suppressive function is evidenced by the development of fatal autoimmune disease as a result of reduced suppressor function in CTLA-4-deficient mice³⁰⁹ as well as treatment of CTLA-4 blocking antibodies for the action of human T_{reg}.³²² Finally, the induction of effector cell apoptosis as a result of IL-2 consumption is proposed for suppressive function of T_{reg}. T_{reg} cells such as effector T cells require IL-2 to survive and highly express the high-affinity IL-2 receptor containing CD25. However, T_{reg} cells produce no IL-2 and therefore are reliant on other sources of IL-2 for survival. In one study, IL-2 consumption by T_{reg} cells resulted in increased Bim-dependent T-cell apoptosis,²⁰⁹ whereas other modes of T_{reg}-mediated apoptosis include perforin production by natural T_{reg} cells¹⁰⁰ and FasL expression by inducible T_{reg} cells.³⁰²

Furthermore, recent studies indicate that T_{reg} cells exert a suppressive effect through modulation of APCs rather than directly modulating effector T cells; a CTLA-4-dependent reduction in CD80/CD86 expression on DCs by T_{reg} cells,^{309,189} but other studies show that T_{reg} cells exert no change in the expression of costimulatory molecules on APCs and addition of functional APCs did not overcome T_{reg} suppression.²⁸⁵

Direct T-cell to T-cell suppression was demonstrated using peptide-MHC tetramer stimulation in the absence of APCs.²¹⁷ Further research may clarify possible contributions of APCs to act as target for T_{reg} suppression; however, it is evident that T_{reg} cells can suppress T cells directly.

ADAPTIVE IMMUNE MEMORY

Two features that define the adaptive immune system and distinguish it from the innate immune system are (a) the exquisite specificity for antigen and (b) the establishment of immunologic memory. Immunologic memory is perhaps the most important consequence of the induction of an adaptive immune response. As a result of clonal expansion of antigen-specific B or T lymphocytes, and a lower activation threshold for memory cells, the immune system can respond more rapidly and efficiently to previously encountered pathogens. This capacity of B and T cells to adapt to a previously encountered antigen is the basis for vaccination. Memory B and T cells generated after infection or vaccination are generally long-lived. In humans, memory T-cell responses (or circulating antibody titer) can be detected decades after pathogen exposure, under conditions where subsequent reexposure to (subclinical infection with) the organism or persistent infection is unlikely. Memory B and T cells directed to an antigen are usually present at a frequency 100 to 1,000 times higher than the corresponding naïve immune cell precursors of memory T and B cells. The factors controlling the formation/duration of the memory immune responses are not yet well understood, but several cytokines may play an important role in maintaining the viability and basal (homeostatic) proliferation of memory cells.

B-CELL MEMORY

The phrase "B cell memory" is often used as shorthand for the mechanisms that lead to long-term humoral immunity. The following two principal mechanisms exist: (a) specific memory B cells expressing BCR to viral antigens, so that viral infection leads to activation of specific B cells and ultimately the production of high-affinity, class-switched antibody to virus; and (b) preexisting serum and tissue high-affinity, class-switched antibody to virus, probably from long-lived plasma cells in the bone marrow. We consider each in turn.

MEMORY B CELLS

Memory B cells express class-switched, somatically mutated surface antibody and can be detected as antigen-specific cells using labeled antigen and a technique such as flow cytometry.¹⁸² They are in a resting state and do not secrete antibodies unless stimulated by antigen. When this stimulation is carried out *in vitro*, memory B cells can be readily detected by enzyme-linked immunospot (ELISPOT) assays. In mice, multiple subtypes of memory B cells have been defined by a number of cell surface markers and gene activation markers.¹⁸² After clearance of virus on first exposure, memory B cells accumulate in the spleen and other lymphoid tissues. Reexposure to virus leads to rapid secondary antibody responses to viral antigens. This response arises because of rapid proliferation and differentiation

of memory B cells in a CD4⁺ T-cell–dependent manner. The specific B-cell population of spleen and lymph nodes expands massively, and differentiation to plasma cells generates a burst in specific antibody production and in antibody levels. Therefore, repeated exposure to antigen is one way in which memory B cell levels can be maintained.

Although controversies have existed over the years, it appears that memory B cells can be long-lived, even in the absence of antigen. An elegant experiment by Maruyama et al.¹⁷³ is persuasive. Mice were engineered so the memory B cells expressing a BCR against antigen 1 could be switched *in vivo* to express a BCR specific for antigen 2. B cells expressing BCR to antigen 2 were identified as persisting in the mice as well as B cells expressing BCR to antigen 1, although the mice had never encountered antigen 2. It should also be noted that BCR expression is required for B-cell survival,¹⁵³ so the possibility exists that nonspecific BCR stimulation, perhaps via a low affinity antigen interaction, is needed for persistence of B-cell memory. Alternatively, the BCR may receive a signal from another molecule such as a cytokine or a molecule such as a B-cell activating factor (BAFF).

One interesting phenomenon related to memory B cells is that of original antigenic sin, (OAS), which was first proposed to describe a phenomenon whereby an individual, originally infected with a virus and then later with variant of this virus, makes an antibody response during the second viral infection that reacts more strongly to the original virus than the newer variant.⁶⁰ It is suggested that boosting of memory B cells against the first virus may interfere with the activation of naïve B cells to the second virus by an undefined mechanism, resulting in a condition that specific antibody responses against the second virus will not be as great compared with a naïve host that has never encountered the first virus. OAS has been reported in both humans^{76,102} and animals,⁷⁷ although a recent study found no evidence of OAS in healthy adults receiving influenza vaccination.³¹¹

LONG-LIVED PLASMA CELLS

Plasma cells are terminally differentiated, nondividing cells able to secrete relatively large amounts of antibody. Two populations of plasma cells exist. Short-lived plasma cells survive for only a few days, produce antibody in extrafollicular foci, and are probably crucial in the very early response to pathogen.¹⁶⁸ In mice, a second population of plasma cells, secreting high-affinity antibody, is long-lived. Irradiation experiments show that the half-life of plasma cells secreting antibody to LCMV was 94 days in the bone marrow and 172 days in the spleen.²⁶⁶ Pulse chase experiments show that plasma cells secreting specific antibody to ovalbumin survived without cell division for a minimum of 3 months.¹⁷¹ These half-lives constitute a sizable proportion of the total lifespan of the mouse. It may be that plasma cells live for many years in humans and contribute to the maintenance of antibody levels over decades.⁹⁷ The bone marrow niche appears to provide survival signals to plasma cells, because *in vitro* such cells survive for only a few days. Another hypothesis is that the pool of plasma cells is being continually replenished from specific memory B cells that are undergoing antigen-independent or bystander activation.¹⁹ These two hypotheses are not mutually exclusive, and it is possible that multiple mechanisms are involved in maintaining serum antibody levels.

LONG-TERM HUMORAL IMMUNITY

Humoral responses can be measured in the sera of humans many years after the last known contact with the pathogen (Table 9.6). Similarly, many vaccines induce serum antibody responses that are present decades later.²²³ A key question has been: Are these responses maintained by intrinsic mechanisms or is there a periodic boosting of immunity through contact with antigen? This question can be difficult to answer given the

TABLE 9.6 Humoral Response to Acute Viral Infection in Humans

Example	Virus family	Persistence of antibody
Systemic infections		
Chikungunya	<i>Alphaviridae</i>	30 yr
Rift Valley fever	<i>Bunyaviridae</i>	12 yr
Dengue	<i>Flaviviridae</i>	32 yr
Yellow fever	<i>Flaviviridae</i>	75 yr
Measles	<i>Paramyxoviridae</i>	65 yr
Mumps	<i>Paramyxoviridae</i>	12 yr
Polio	<i>Picornaviridae</i>	40 yr
Hepatitis A	<i>Picornaviridae</i>	25 yr
Smallpox	<i>Poxviridae</i>	40 yr
Vaccinia	<i>Poxviridae</i>	75 yr
Rubella	<i>Togaviridae</i>	14 yr
Mucosal infections		
Coronavirus	<i>Coronaviridae</i>	12 mo
Influenza	<i>Orthomyxoviridae</i>	30 mo
RSV	<i>Paramyxoviridae</i>	3 mo
Rotavirus	<i>Reoviridae</i>	12 mo

RSV, respiratory syncytial virus; yr, year; mo, month.

Modified from Slifka MK, Ahmed R. Long-term humoral immunity against viruses: revisiting the issue of plasma cell longevity. Trends Microbiol 1996;4:394–400.

unknowns associated with typical human contacts with pathogens. For at least two vaccines, serum antibody levels appear to be maintained in the absence of antigen boosting.⁵³

A large cross-sectional study of poliovirus immunity in Sweden, a country from which the virus has been eradicated, and which used inactivated poliovirus only as a vaccine, showed substantial anti-poliovirus antibody titers in all age groups.²⁶ Virtually no differences in titers were found in the different age groups, indicating the maintenance of antibody titers over decades in the absence of further vaccination or exposure to live virus. Notably, in the same study, declining antibody titers against tetanus and diphtheria were observed.

Two studies have looked at smallpox vaccination using vaccinia virus.^{54,105} Vaccinia is an excellent model for investigating immune memory, because the virus is typically cleared from the site of infection within a month, does not persist, and does not spread systemically in healthy individuals. Immunization with vaccinia ceased in 1972 and smallpox has been eradicated. Specific memory B cells could be detected more than 60 years after vaccination.^{53,54} Furthermore, memory B cells seemed to show a bimodal kinetics. A drop from peak responses occurred at vaccination to an approximately 10-year time point, but stable levels were seen between 10 and 60 years. Serum antibody responses could be identified at 60 to 75 years after vaccination.^{54,75,105} Because overall antivaccinia antibody levels correlated well with neutralizing antivaccinia antibody levels, it was postulated that different specificities may be equally well preserved. Furthermore, the results suggest, as originally posited by Jenner more than 200 years ago, that protective immunity against lethal smallpox infection may be lifelong.

Finally, it is apparent from Table 9.6, that mucosal antibody responses are much shorter-lived than are serum responses. This may indicate that plasma cells initially produced at mucosal sites migrate to the bone marrow and contribute less to mucosal antibody production.

T-CELL MEMORY

Unlike the immunoglobulin receptors on B cells, the genes encoding the TCR on CD4⁺ T cell and CD8⁺ T cells do not undergo any additional somatic mutations, and memory T cells do not, therefore, exhibit affinity maturation after antigen encounter. Memory T cells distinguished functionally from their naïve precursors by being present at increased frequency (a result of clonal expansion of naïve antigen-specific T cells), and by their lower activation threshold (i.e., decreased requirement for CD28 co-stimulation) to trigger cell proliferation and differentiation.²⁴⁷ Certain memory T cells can also rapidly express effector activity (e.g., proinflammatory/antiviral cytokines, such as IFN- γ and TNF- α) within hours after TCR engagement on these T cells, and without DNA synthesis (additional cell proliferation). Naïve T-cell activation and proliferation and memory T-cell population formation and maintenance are controlled by three cytokines: IL-2, IL-7, and IL-15.²⁴⁴ The receptors on T cells for these three cytokines have a common feature—these heterodimeric and trimeric receptors have a common signaling subunit, the so-called γ chain (γ_c), which participates in both ligand (cytokine) binding and Janus Kinase (JAK)/STAT-dependent signal transduction.¹⁴⁹ IL-2/IL-15 can drive proliferation of activated naïve T cells after

TCR engagement (IL-4, which engages another member of the γ_c family of cytokine receptors, will also support proliferation of differentiating T_H2 CD4⁺ T cells). Current evidence suggests that once memory T cells are formed, they can undergo basal/homeostatic low-level proliferation, which is IL-15-dependent, and long-term memory T-cell viability (i.e., suppression of apoptosis) is supported by IL-7, which upregulates/sustains the expression of anti-apoptotic Bcl-2 gene family members in the developing memory T cells.

Although activated naïve T cells give rise to both effector (T_E) and memory (T_M) T cells, the relationship of the two naïve T-cell products is unclear (i.e., we do not know if T_E give rise to T_M in a linear progression, or if T_E and T_M are separate cellular subsets).²⁴⁷ T_M can be distinguished from naïve T cells and, to a lesser extent, from T_E by the expression of certain cell surface molecules (e.g., isoforms of CD45) differentially expressed on T_M and naïve T cells. Several lines of recent evidence indicate that a further subdivision may exist of CD4⁺ T cell and CD8⁺ T cell T_M into central memory (T_{CM}) and peripheral effector memory (T_{EM}) populations.¹⁵⁵ T_{CM} express cell surface molecules such as CD62L and the chemokine receptor CCR7, which would facilitate the circulation of T_{CM} from the blood into the SLOs (particularly the lymph nodes). So, T_{CM} would mimic the circulation pattern of naïve T cells (from the blood into secondary lymphoid organs (SLO) and then back into the bloodstream), and would respond to antigen delivered to the SLO; and, as with naïve T cells, T_{CM} may require both activation and cell division to express effector activity. By contrast, T_{EM} do not display the homing receptors for the SLOs, and have been suggested to reside primarily in the blood and peripheral tissues, where they can rapidly respond to a pathogen at the initial site of pathogen entry in the periphery. Unlike T_{CM}, the T_{EM} appear to undergo limited proliferation in response to antigen, but rapidly express antimicrobial effector activity in response to infection. Although this classification of memory T cells (T_{CM}/T_{EM}) based on cell surface markers is useful as an experimental framework, evidence from the analysis of the immune response to virus infection in humans suggests that considerable heterogeneity exists in cell surface marker expression on circulating T cells in the peripheral blood.²⁹² Therefore, under conditions of natural infection (and possible vaccination) the memory T-cell response may consist of a continuum of activation and differentiation states—at least, based on activation/differentiation marker expression.

MEMORY CD8⁺ T CELL DIFFERENTIATION

Memory CD8⁺ T cells are characterized by distinct features in terms of quantity and quality of responses from their naïve precursors.^{3,21,136} Substantial progress has been made in defining the phenotypic and functional changes involved in the course of memory CD8⁺ T-cell differentiation. During the acute phase of viral infection, antigen recognition and inflammatory signals such as type I IFN and IL-12 induce a rapid and substantial clonal expansion of naïve antigen-specific T cells, which develop into effector T cells at 1 to 2 weeks after infection.^{133,148} In this expansion phase, there are several changes in phenotype and function of antigen-specific T cells to acquire memory T cells. At the peak of CD8⁺ T cell responses, naïve T-cell expansion leads to two distinct subsets (short-liver effector

cells and memory precursor effector cells). These cells can be defined by expression of the cell surface markers CD127 and KLRG1.^{135,239} CD127 is highly expressed on naïve T cells but appears to be downregulated on all antigen-specific CD8⁺ T cells after activation. These CD127^{lo} T cells consist of KLRG1^{hi} and KLRG1^{lo/int}. Memory CD8⁺ T cells arise from KLRG1^{lo/int} populations by subsequent reexpression of CD127. However, these memory precursor effector cells (CD127^{hi}KLRG1^{lo/int}) efficiently survive the contraction phase, memory T-cell properties, and constitute the majority of the memory T-cell pool. These memory CD8⁺ T cells further differentiate into self-renewing memory T cells, and the extended lifespan depends partly on IL-7/IL-15–dependent homeostatic proliferation having slow cell division and minimal cell number changes.

Recently, factors involved in controlling the differentiation of effector and memory CD8⁺ T cells have been demonstrated. First, T box expressed in T-cells (T bet) has been identified as a transcription factor regulating the differentiation of effector and memory CD8⁺ T-cell responses¹³³: the high levels of inflammation and T-bet promoted effector cell differentiation, whereas mild inflammation and low T-bet generated memory cells. Another T-box transcription factor, Eomesodermin (Eomes), is expressed in a reciprocal manner to T-bet such that it is repressed by inflammatory cytokine, IL-12²⁸⁴ and may play a role in promoting memory responses.¹²⁷ In addition, genetic studies reveal that their function is redundant by promoting both killer T-cell fate and CD8⁺ memory homeostasis.¹²⁶ Lastly, Blimp-1, a regulator of plasma cell differentiation, is required for CD8⁺ T cell differentiation into functional killer cells and is crucial for recall response to reinfection. However, Blimp-1 is not essential for the generation of memory T cells.¹³⁸

VIRAL STRATEGIES TO EVADE THE ADAPTIVE IMMUNE RESPONSE

The immune responses to virus involve complex molecular and cellular interaction between the virus and its host. Therefore, any stage in this interaction could be targeted by a pathogen and used for its own benefit. The systematic study of viral genomes

TABLE 9.7 Viral Strategies to Avoid Host Adaptive Immunity

Escape by mutations
Escape by latency
Escape by destruction of immune cells
Escape by subverting antigen processing and presentation
Inhibition of T cell–mediated target cell lysis
Inhibition of inflammatory responses via modulation of cytokine action
Inhibition of humoral immunity by virally encoded Fc receptor, complement receptor/control protein

reveals that most viruses have evolved means of escaping or subverting immune defenses, and that some of them have many genes devoted to this purpose. Although the large, more complex DNA viruses encode viral proteins to avoid immune recognition, RNA viruses usually generate small numbers of proteins as compared to DNA virus with large genomic materials. Regardless of whether they are DNA and RNA viruses, it seems that many, and possibly all, pathogens that cause chronic infections have evolved strategies to subvert the immune responses of the host as listed in Table 9.7. These strategies include evasion of humoral and cellular immunity by antigen variation, interference with antigen processing and presentation, and modulating the production of cytokines. Viral proteins that interfere with class I MHC antigen presentation and modulate inflammatory cytokines are listed in Tables 9.8 and 9.9. Understanding of the complex interactions between the immune system of the host and the invading viral pathogen will eventually enable researchers to devise better strategies for preventing viral diseases.

As described above, effector function of CD8⁺ T cells and CD4⁺ T_H1 cells plays a pivotal role in controlling viral infection. One critical way to induce virus-specific T-cell responses deals with the generation of antigenic peptides derived from viral products to CD8⁺ T cells and CD4⁺ T_H1 cells. The generation of antigenic peptides also involves the

TABLE 9.8 Inhibition of Antigen Presentation Via the Major Histocompatibility Complex Class I Pathway

Steps to Interfere with MHC class I pathway	Virus-encoded proteins
Inhibit MHC class I synthesis	Lentivirus (Vpu)
Inhibit transporter associated with antigen processing (TAP)	
–Expression	EBV (vIL-10), HCMV (UL111A)
–Function	HCMV (US6), HSV (ICP47)
Inhibit MHC class I transport	
–Retain MHC class I in the ER	HCMV (US3), adenovirus (E3-19K)
–Retain MHC class I in the pre-Golgi compartment	MCMV (m152)
–Dislocate MHC class I to the cytoplasm	HCMV (US11, US2)
–Dislocate MHC class I to lysosomes	MCMV (m6/gp48)
–Bind to cell surface MHC class I molecules	MCMV (gp34)
–Increase endocytosis of MHC class I molecules	HIV (nef), HHV-8 (K3, K4)

TABLE 9.9 Viral Modulation of the Cytokine System**Ways to interfere with cytokine function****Interrupt cytokine production**

- Interfere with cytokine and chemokine synthesis
- Inhibit the generation of functional cytokines

Interfere with cytokine action

- Encode homologs of cytokines and cytokine receptors
 - Type I interferon (IFN) homolog: VV (B18R)
 - IFN- γ homolog: VV (B8R)
 - Interleukin (IL)-6: KSHV (K2)
 - IL-8 homolog: HCMV (UL146, 147)
 - IL-10 homolog: EBV (BCRF1), HCMV (UL111A)
- Generate soluble cytokine receptors to neutralize cytokines
 - IFN- γ receptor: myxoma virus (MT-7)
 - IL-1 β R: VV WR (B15R)
 - TNFR homolog: orthopoxvirus (CrmB, CrmD)

Interfere with cytokine effector function

- Alter cytokine signaling pathway

HCMV, human cytomegalovirus; EBV, Epstein-Barr virus; IFN, interferon; IL, interleukin; TNFR, tumor necrosis factor receptor; Crm, cytokine response modifier.

class I II MHC-dependent presentation of antigenic peptides to CD8⁺ and CD4⁺ T cells. The details for virus-mediated class I MHC and class II MHC antigen presentation is well described in.^{131,162} A second critical way for successful induction of antiviral T-cell responses involves the production of cytokines such as IFN- γ , which is pivotal for protective CD8⁺ T cells and CD4⁺ T_H1 cells. It has been well established that IFN- γ production is positively influenced by IL-12, but is negatively regulated by IL-10. It is conceivable that viruses exploit strategies to mimic the immunomodulatory cytokines, IL-12 and IL-10, to modulate virus-specific T-cell responses.⁴ Among the multiple ways to subvert adaptive T-cell responses, we will describe viral immune evasion strategies to evade innate immunity by interfering with the recognition of viral constituents by pattern-recognition receptor (PPR) and the initiation of inflammatory responses.

Innate immunity consists of multiple cellular sensors and signaling pathways, which lead to activation of early host defense mechanisms in response to viral invasion. These early antiviral responses result in the production of type I IFN that activates numerous transcription factors to induce the inflammatory gene expression.^{23,128,140} Thereby the early detection of viruses is the main role of innate immune cells by sensing virus-derived molecules and triggering host defense mechanisms. These sensors include the RIG-I-like helicase family for recognition of viral RNA as well as TLR and NOD-like receptor pathways for sensing various virus-derived molecules.

Activation of the interferon response is triggered by the detection of viral pathogen-associated patterns. All of the PRRs initiate signaling pathways that converge at the activation of transcription factors, IRF-3, IRF-7, and NF- κ B. The activation of these transcription factors leads to the expression of IFN- β . IFN- β initiates an anti-viral effector program in the infected cells and neighboring cells by the expression of numerous IFN-stimulated genes (ISGs). Because the host has evolved strategies for detecting and responding to viral infection, viruses

constantly evade TLR signaling to inhibit antiviral IFN action. One best example is the cleavage of IPS1 by HCV NS3/4a protease to block RIG-I signaling.^{82,90} The influenza A virus NS1 protein inhibits RIG-I-mediated PRR signaling by direct interaction,^{89,206} whereas paramyxovirus V protein binds and inhibits MDA-5 to abrogate PPR signaling.^{42,43}

VIRAL EVASION OF HUMORAL (B CELL) IMMUNITY

Viruses use a number of mechanisms to evade humoral immune responses, and viral neutralizing antibodies in particular (reviewed in¹⁵⁶). Viral strategies to evade neutralizing antibody responses to the viral surface proteins include (a) mutation of surface proteins by antigenic drift and shift, and recombination, most notably for highly variable viruses such as influenza virus, HIV and HCV; (b) masking of conserved epitopes; (c) glycan shielding as seen for HIV and Ebola viruses for example; (d) surface protein decoys that may “mop up” neutralizing antibodies under certain conditions, for example as with HBV; (e) original antigenic sin; (f) irregular surface protein spacing that tends to reduce immunogenicity; and (g) multiple surface proteins and virus forms, for example poxviruses encode multiple proteins for entry. Viruses can also evade humoral responses by spreading directly between cells, upregulating and hijacking host complement regulatory proteins, encoding antagonistic Fc and complement receptors and inducing immunosuppression.

VIRAL EVASION OF CELLULAR (T CELL) IMMUNITY

Escape by Subverting Antigen Processing and Presentation

A number of viruses have devised strategies to impair presentation of their antigens by the MHC class I pathway, thereby reducing activation of antigen-specific CD8⁺ T cells as well as recognition of virus-infected cells by CD8⁺ T cells. This stresses the importance of this cell subset for antiviral defense. Nearly every step of the MHC class I presentation pathway can be interfered with, and some viruses encode multiple proteins that act at different levels of the MHC class I processing pathway (Table 9.8): (a) inhibition of MHC class I synthesis, (b) antigenic peptide generation, (c) transporter associated with antigen processing, and (d) the cell surface expression of MHC class I molecule expression. Although interference of the MHC class II antigen processing pathway by virus is less common, some evidence indicates that viruses are able to inhibit this pathway.

Inhibition of Class I or II Major Histocompatibility Complex Synthesis

Viral proteins, including HIV Tat protein, have been reported to suppress or inhibit MHC gene promoter activity.¹²⁰ It has been shown for HIV Tat protein that the activity of the MHC class I gene promoter was decreased up to 12 times. With respect to the inhibition of MHC class II expression, human cytomegalovirus (HCMV) can impair MHC class II expression through two distinct pathways. MHC class II molecules

are expressed only on a subset of cells, and this expression is regulated at the transcriptional level through control elements that include those that allow both constitutive and cytokine-induced transcription of the MHC class II genes. The MHC class II transactivator (CIITA) is essential for constitutive and induced transcription, and is the rate-limiting factor of MHC class II production. One of the four promoters controlling CIITA production is activated by IFN- γ , which, on binding to its receptors, triggers a signaling cascade through Janus kinases, leading to transcription of IFN-inducible genes. The inhibition of IFN- γ -stimulated MHC class II expression occurs by two different mechanisms: (a) decreased Janus kinases¹⁸⁶ and (b) interference with the CIITA promoter.¹⁵⁸

INHIBITION OF ANTIGENIC PEPTIDE GENERATION

The metalloproteases, CD10 (endopeptidase) and CD13 (aminopeptidase N), are downregulated during HCMV infection.²¹⁶ CD10 expression is apparently blocked at the transcriptional or translational level, whereas CD13 seems to be retained within the ER compartment. These endopeptidases play a role in peptide processing in both MHC class I and II antigen presentation pathways. Both CD10 and CD13 peptidases are expressed on the cell surface and trim antigenic peptides to a size that allows their binding to the groove of class I or II molecules.

Inhibition of Transporter Associated with Antigen Processing

The peptide transporter TAP is needed to shuttle peptides from the cytoplasm to the ER, in which they associate with MHC class I determinants. TAP peptide transport is inhibited by a protein of HCMV, US6, which acts from the luminal site of the ER. HCMV US6 protein specifically binds at the ER-luminal loops of TAP signals across the membrane to the nucleotide-binding domains. This binding prevents ATP hydrolysis of TAP, which is necessary for peptide transport.

The ICP47 polypeptide from HSV inhibits TAP by binding to TAP's peptide binding site, thus preventing its association with other peptides. This results in an insufficient number of peptides in the ER for binding to MHC class I molecules. In contrast, TAP-independent peptide loading of MHC class I molecules is not affected by US6 or ICP47. As described below, EBV encodes a protein that weakly binds the IL-10 receptor. As with cellular IL-10, the EBV protein reduces expression of TAP and of MHC class II.

INHIBITION OF MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I CELL SURFACE EXPRESSION

Modulation of MHC class I expression has been reported in at least three viral systems: adenoviruses, HCMV, and HSV. HCMV US3 protein, a type I membrane protein, prevents maturation of MHC class I molecules by retaining them in the ER compartment. US3 protein binds to MHC class I molecules in a transient fashion, but retains them efficiently in the ER. The US3 luminal domain is responsible for ER retention of

US3 itself, whereas both the US3 luminal and transmembrane domains are necessary for retaining MHC class I in the ER. In contrast to HCMV US3 protein, HCMV US2 and US11 catalyze the dislocation of MHC class I products, resulting in their rapid degradation. US11 protein uses its transmembrane domain to recruit MHC class I products to human homologue of yeast Der1p, a protein essential for the degradation of MHC class I molecules catalyzed by US11, but not by US2. HCMV US2 has been shown to differentially affect surface expression of MHC class I but only targets membrane-bound (not soluble) HLA-G1 antigen for degradation.

Adenovirus expresses a protein E3/19K, which is an ER-retained protein; it has a cytosolic ER-retention signal in the C-terminus of its cytoplasmic tail (-DEKKMP). The 19K binds certain murine MHC class I molecules (e.g., A2, K^d, L^d, but not K^k, or D^d) and holds them in the ER. This results in decreased MHC class I expression and decreased CTL recognition. An immediate early gene product of HSV, the ICP47 gene product, interferes with transport of peptides from the cytoplasm to the ER, thereby depriving MHC class I molecules in the ER of peptides. This results in both the ER peptides and destabilization and retention of MHC class I molecules in the ER.

VIRAL EVASION OF IMMUNE EFFECTOR MECHANISMS

Interference with Cytokine Functions

Cytokines (e.g., IFN and TNF) induce intracellular pathways that activate an antiviral stage or apoptosis, and thereby limit viral replication. A large number of cytokines induce mechanisms that enhance immune recognition and/or immune responses that protect against viral infection. In addition, antiviral cytokines play a pivotal role in removal of infected cells by NK cells or CTL. Therefore, it is not surprising that viruses use immune evasion strategies to control the function of cytokines.

Recently, viral modulation of cytokines by several viruses has been reported. Three different mechanisms have been shown to affect the activity of cytokines (Table 9.9). Viruses produce cytokine homologs, which bind to the same cytokine receptors. Alternatively, viruses generate antigens that mimic cytokine receptors and, thus, neutralize the corresponding factors. Finally, they can directly interfere with the action of cytokines by generating soluble cytokine-binding proteins. The functions of viral homologues of cytokine and their receptors are diverse. The virus-encoded cytokine homologs might be involved in inactivating inflammatory cytokines or redirecting the immune responses.

Inhibition of cytokine production has been shown by poxvirus; cowpox virus (CPV) cytokine response modifier A (CrmA) protein inhibits the production of caspase-1, which prevents the proteolytic cleavage of prointerleukin-1 β (pro-IL-1 β) to mature IL-1 β . In addition, the attachment of measles virus to its cellular receptor, CD46, a complement regulatory protein, inhibits the production of IL-12. Many virus-encoded mechanisms are involved in blocking the effector functions of cytokines, such as the antiviral state induced by IFN or apoptosis triggered by TNF, and intracellular antagonists of TNF or IL-1/Toll-like receptor (TLR) signaling. Interestingly, LMP-1

of EBV recruits components of tumor necrosis factor receptor (TNFR) and CD40 signal-transduction machinery, which induces biological responses to help viral replication.

RECEPTOR BINDING AND MODULATION OF IMMUNE CELL FUNCTION

Measles virus binds to, and enters, monocyte/macrophages using the CD46 molecule (a C3b receptor) as its receptor for entering cells; cross-linking CD46 inhibits the production of IL-12 by macrophages. Therefore, measles-induced immune suppression may be related to the failure of infected APCs to make the proinflammatory cytokine IL-12. Another IL-12 homolog, UL111A, is encoded by HCMV.

CYTOKINE AND CYTOKINE RECEPTOR HOMOLOGS

Alterations in cytokine function represent a newly appreciated mechanism of evasion. One of the most striking examples of this mechanism has been reported for EBV, has apparently cannibalized the gene for the human IL-10 cytokine. The viral genome, gene BCRF1, encodes a protein with 70% amino acid homology to human IL-10, which inhibits cytokine production by T_H1 type T cells and monocytes (macrophages) through its action on macrophage function. IL-10 also activates B lymphocytes and upregulates BCL-2. The viral IL-10 has all of the same activities as human IL-10.

Our understanding of the role of viral immunomodulatory proteins in the context of infection is limited, mainly because of the lack of appropriate experimental models of infection. In many cases, we can only predict the *in vivo* function of a viral protein in view of a known function of cytokines. As expected, inactivation of poxvirus-soluble cytokine receptors (e.g., the myxoma virus vTNFR and vIFN- γ R, or the vaccinia virus vIFN- α/β BP) leads to virus attenuation. The attenuated phenotype of the myxoma virus vIFN- γ R (M-T7) mutant might also be attributed to the ability of M-T7 virus to bind chemokines, which is consistent with increased leukocyte recruitment to sites of infection. The consequences of the inactivation of a viral immunomodulatory protein on the outcome of infection, however, might be unpredictable. Deletion of vaccinia vIL-1 β R exacerbates vaccinia virus infection in a mouse intranasal model because of enhanced systemic activity of the proinflammatory cytokine IL-1 β , which might cause increased fever and weight loss, leading to enhanced mortality of the infected host. This indicates that some viral immunomodulatory proteins might downregulate immune-mediated pathology to favor equilibrium with the host, rather than to increase viral replication.

VIRUS-INDUCED IMMUNE DYSREGULATION AND AUTOIMMUNE DISEASE

Chronic diseases can result when the immune system is overly active, often causing the affected tissues to be inflamed and abnormally infiltrated by lymphocytes and other leukocytes.

However, no active infection is associated with such diseases. Therefore, these diseases are caused by the immune system itself, which attacks cells and tissues of the body. Chronic diseases of this kind are known as autoimmune diseases, as they are caused by immune responses directed toward self-components of the body. Several genetic risk factors and protective elements have shown to influence the susceptibility of autoimmune disease.⁷⁴ However, a considerable discordance in incidence of autoimmune disease comparing identical twins indicates that, in many cases, additional factors such as environment modulators could influence the incidence of autoimmune diseases.⁴⁷

Indeed, viral infections, particularly chronic viruses, are shown to enhance autoimmune disease in susceptible individuals, as infections frequently induce strong inflammatory responses in various organs.^{203,210} There are several major pathways through which viruses can initiate or more likely modulate autoimmunity: (a) direct infection of target cells/organs can cause the release of sequestered autoantigens and enhance antigen presentation; (b) local inflammation might alter the repertoire of self-epitopes presented by APCs by altering Ag degradation properties of the proteasome; (c) Presentation of pathogen epitopes with structural or sequential similarity to self-epitopes might specifically activate autoreactive lymphocytes. However, some viral infections can also act to ameliorate autoimmunity. There are several reports supporting the association of autoimmune diseases with viral infection. Indeed, associations with infectious agents have been suggested for a multitude of autoimmune diseases, including type 1 diabetes (T1D), multiple sclerosis (MS), and ankylosing spondylitis. However, attempts to establish a direct epidemiological, statistically relevant association between microbial infections and various autoimmune disorders have been unsuccessful thus far.

Recently, several animal models for human autoimmune diseases have been established to elucidate the role of molecular mimicry in initiating autoimmune diseases. In transgenic animals that express specific target antigens, challenge with pathogens containing identical or similar antigens act as a triggering factor for the autoimmune disease process.⁴⁶ The induction of autoimmune disease in these models requires sufficient numbers of autoaggressive lymphocytes. Thereby, it is likely that infection with a pathogen having molecular identity to a target self antigen can result in the generation of more lymphocytes with high avidity to the identical transgenic target antigen. In the rat insulin promotor (RIP)-LCMV model for type 1 diabetes, the avidity of self-reactive lymphocytes has been demonstrated to determine the course of disease. RIP-LCMV mice express the glycoprotein or nucleoprotein of LCMV under the control of the RIP, specifically in the β cell of the pancreatic islets of Langerhans.²⁹⁹ However, even in the absence of possible thymic expression of target antigen, mechanism of peripheral tolerance can result in a certain degree of unresponsiveness to the identical antigen present on the triggering virus that might prevent aggressive immune responses. In addition, infection with pathogens with similar but not identical structures might overcome tolerance induced by the host. This has been demonstrated in the development of autoimmune hepatitis in the CYP2D6 mouse model, which is associated with the molecular mimicry. In the model of CYP2D6, adenovirus (Ad-2D6) expressing human cytochrome P450 (CYP) 2D6 (CYP2D6) was used to trigger autoimmune liver damage, and CYP2D6

is a major natural autoantigen in autoimmune hepatitis type 2.^{170,320} As targets, wild-type FVH mice, which express mouse CYP isoenzymes with a structural and sequential similarity to human CYP2D6 (molecular mimicry), or transgenic CYP2D6 mice, which express additional human CYP2D6 (molecular identity). However, it is yet to be known whether autoimmunity initiated by the molecular mimicry generates enough autoaggressive lymphocytes with sufficient avidity to cross the threshold for clinical autoimmune disease.

INTRODUCTION TO VIRAL PATHOGENESIS

Viral pathogenesis is the series of steps that occurs when a virus infects the host. Viruses are obligate parasites of living cells that cannot live independent of an intricate relationship with an infected cell. The cells targeted by viruses during infection survive, differentiate, and function in a tissue that has an intimate relationship with other tissues and physiologic processes in the body. Thus, in the same sense that viruses are obligate parasites of living cells, they are obligate parasites of tissues in living organisms. Living in tissues and spreading from host to host represent processes only approximated in cell culture or biochemical experimentation. The study of viral pathogenesis elucidates this special relationship between the virus and the intact host.

The term *pathogenesis* refers to the processes related to disease induction; therefore, *viral pathogenesis* often refers to disease induction by a virus rather than the process of infection *per se*. However, viral infection does not always result in apparent or immediate disease, and the border between infection and disease becomes less clear as we learn more. It is most useful to consider the pathogenesis of infection independently of whether or not severe or immediate disease is induced. As the pathogenesis of infection is analyzed, the pathogenesis of disease can be considered as a subset of events that occur *in vivo* during infection. Fundamentally important mechanisms are revealed when one considers how the pathogenesis of infection differs between the host with asymptomatic infection or minimal disease and the host doomed to suffer severe consequences of viral infection.

Viral pathogenesis is the integrated result of many complex factors unique to a particular virus, a particular species, and an individual host. The interplay of these factors determines the nature of infection, whether disease occurs, and the severity of disease. In many cases, individual factors involved in pathogenesis can be studied in detail. For example, the crystal structure of a viral immune evasion protein allows predictions as to protein function during infection *in vivo*. However, definitive pathogenesis experiments often falsify such predictions. Thus, all conclusions derived from reductionist experiments utilizing molecular and biochemical approaches need to be validated in living organisms to understand viral pathogenesis.

The complexity of directly testing molecular mechanisms *in vivo* has been a significant stumbling block for pathogenesis research. The difficulty of doing definitive pathogenesis experiments that prove a molecular mechanism *in vivo* has resulted in pathogenesis research being relegated at times to a lesser status as a phenomenological science when compared to studies of molecular and biochemical mechanisms. However, in the end, infection occurs in the intact host; thus, events *in vivo* are highly relevant. With the development of new tools, in particular those that allow genetic analysis of pathogenesis from both the viral and host standpoint, pathogenesis research has rapidly evolved into a mechanistic science. Moreover, classical studies of pathogenesis have often stood the test of time and are useful at a minimum for defining the fundamental questions to be addressed using molecular pathogenesis approaches.

Goals of This Chapter

This chapter will focus on integrating classical concepts of pathogenesis with more current molecular understanding of

viruses. Viral pathogenesis is the subject of many authoritative texts, and the reader is referred to one such text for detailed treatment of many of the important concepts developed here in necessarily shorter form.^{195,196} There is a rich history of how the initial observations that form the basis for our current understanding of viral pathogenesis were made.¹⁹⁶ These founding studies are important to our understanding of the pathogenesis of infection as well as to major advances in human health such as the elimination of smallpox and the development of vaccines against diseases such as polio, measles, mumps, rubella, hepatitis B virus (HBV), and human papillomavirus. Exposure to the historical roots of pathogenesis research is strongly recommended for those who wish to delve into viral pathogenesis as a career or avocation.

Because it is impossible to provide a detailed description of the pathogenesis of all viral infections in a single chapter, the goal of this chapter is to provide a conceptual framework for understanding viral pathogenesis. Principles will be defined and then examples provided from a broad range of infections. For details of specific viral infections, refer to chapters on individual viruses. This chapter will specifically focus on the pathogenesis of infection with nucleic acid-containing viruses in mammals. There is a rich body of knowledge on plant viral diseases and prion diseases that will not be addressed in this chapter.

DEFINITIONS AND CONCEPTS IN VIRAL PATHOGENESIS

The literature on pathogenesis is extensive and more than 100 years old. A search of the recent literature accessed by Entrez using the term *viral pathogenesis* pulls up more than 426,000 references, whereas a search of *viral disease* pulls up more than 695,000 references. Within this complex and voluminous literature, terms are used in multiple ways. Often the utilization of terms is predicated on historical factors rather than more up-to-date considerations. We will therefore begin by defining terms as they will be used in this chapter.

Productive, Abortive, and Latent Infection

Infection is the process by which a virus introduces its genome into a cell. Infection is *productive* if new infectious virus is made and *abortive* if no new infectious virus is produced. Infection is *latent* if the production of infectious virus does not occur immediately but the virus retains the potential to initiate productive infection at a later time. The process of reinitiating a productive infection cycle from the latent state is termed *reactivation*. Latency is not merely a slow productive replication cycle; latency represents a unique transcriptional and translational state where infectious virus is not present, but where a productive replication cycle can be reinitiated when the need arises. A cell is permissive if it can support productive infection and nonpermissive if infection cannot occur at all or is abortive.

Acute Versus Chronic or Persistent Infection

Acute infection occurs when a virus first infects a susceptible host (Fig. 10.1). *Chronic* or *persistent infection* is the continuation of infection beyond the time when the immune system might reasonably be expected to clear acute infection. The

FIGURE 10.1. Schematic of different patterns of viral infection.

terms *chronic* and *persistent* have been used interchangeably for many years; we will continue this convention. It is important to note that these terms denote the presence of viral infection in the host for long periods but do not provide insight as to the mechanism(s) responsible for prolonged survival of the virus in the host. Mechanisms responsible for chronic infection include persistence of nucleic acid, continuous replication, latency, and reactivation. More than one of these processes may occur at the same time. In some cases, viral nucleic acid can be detected in the host for prolonged periods, although the nature of the infectious process has not been defined (see Fig. 10.1). In such

cases, chronic infection may represent continuous replication, latent infection, abortive infection without clearance of residual nucleic acid, or perhaps some as-yet-unidentified form of viral infection.

In some cases, as for HBV or hepatitis C virus (HCV), a proportion of persons become chronically infected while others are cured. In these cases, the transition from acute to chronic is arbitrarily defined as the time when most patients have cleared acute infection. In other cases, essentially all hosts become chronically infected, as is seen with herpesviruses or lentiviruses such as human immunodeficiency virus (HIV). In this case, the transition between acute and chronic infection is defined as the time required for clearance of the initial burst of viral replication and establishment of equilibrium between the host and the virus.

There are two primary mechanisms for establishment of chronic infection: *continuous replication* and *establishment of latency*. During latent viral infection, the virus has a genomic and transcriptional strategy, often involving restricted viral gene expression, which allows the genome to survive even when lytic replication is not occurring. Examples include the proviral form of retroviruses or the circular episomal form with selective expression of viral genes observed for herpesviruses such as Epstein-Barr virus (EBV) and herpes simplex virus (HSV). Often, latently infected cells express no viral proteins, making latency immunologically silent. This is the ultimate form of immune evasion, as the host has no known mechanisms for sensing the presence of the virus. To survive and spread from the latently infected cell, the virus must be able reactivate and reinitiate the lytic cycle of gene expression, potentially generating antigens that the immune system can respond to.

To succeed via continuous replication, a virus must generate new infectious virions despite ongoing innate and adaptive immune responses. Even for viruses that utilize the establishment of latency as a primary strategy, intermittent reactivation and replication may be required to maintain latency and to spread from host to host. Some viruses, such as HIV, persist via both continuous replication and establishment of latency, presenting a particularly difficult challenge for the host immune system.^{107,301}

Quasispecies

The mixture of viruses present in the host at a given time is a *quasispecies*. Although it is convenient to think of a virus as a single homogeneous agent, this is not true because both viral RNA and DNA polymerases make errors that generate mutant viruses during infection. The polymerases of RNA viruses are generally less accurate in copying template molecules than those of DNA viruses; mutation may therefore play a greater role in RNA than DNA virus pathogenesis. However, mutation may play a role in the pathogenesis of any virus. The quasispecies generated by mutation is acted on by complex and powerful selective pressures in the host, with some viruses having a survival or fitness advantage over others. The nature of these selective pressures and the pathogenic potential of the selected viruses are important determinants of viral pathogenesis.

Control of Acute Versus Chronic Infection

The distinctions between acute and chronic or persistent infection are very important. The viral genes and host immune

factors that foster or control acute versus chronic infection are distinct. For example, the cytokine interferon- γ (IFN γ) regulates latency and continuous replication of the murine γ HV68 (also referred to as MHV-68) but has at most a minimal effect during acute infection.¹⁶ This indicates that certain host responses are more relevant to chronic than acute infection. Control of either acute or chronic infection may involve responding to viral quasispecies. This is the case for both HIV and HCV infection, presenting the infected host with the overwhelming problem of dealing with many antigenically distinct viruses with different pathogenic strategies. Many viruses, including herpesviruses, papillomaviruses, and retroviruses, use different gene or gene expression patterns to succeed during acute versus chronic infection. For these reasons, it is fundamentally important not to consider chronic infection as a mere continuation of acute infection.

Equilibrium and Nonequilibrium States in Pathogenesis

A fundamental concept in pathogenesis is that acute infection is a nonequilibrium state, whereas chronic infection is a metastable equilibrium between virus and host. During acute infection, both the host response and virus infection change continuously until infection is resolved or progresses to death of the host or establishment of chronic infection. In contrast, chronic infection, once established, is an equilibrium process with viral and host processes balancing each other. In particular, the immune system of the host brings the acute infection under control and delays or prevents a chronic infection from killing the host. Progression of chronic infection to disease often reflects a change in this equilibrium (see Fig. 10.1). Even when the host and virus are in a stable equilibrium, the infectious process is dynamic with host and viral processes balanced on a knife-edge such that small changes in either virus or host can disrupt the equilibrium with devastating consequences.

An example of nonequilibrium and equilibrium states during acute and chronic infection is provided by EBV, a γ -herpesvirus that causes acute mononucleosis in humans. During the acute stage of infection, EBV causes rapid B-cell expansion (a nonequilibrium process) that is then brought under control by the expansion of virus-specific T cells, which act to maintain the virus in a latent state (an equilibrium process). When levels of latently infected B cells are assessed, significant individual-to-individual variation is observed but levels are remarkably constant within a given individual over time. However, when patients are immune suppressed, the level of latently infected B cells increases,¹² suggesting that interactions between the virus-specific T cells and the virus maintain equilibrium during the chronic stage of infection. This balance between immune and viral processes during chronic infection is incompletely understood in most cases and yet is fundamentally important for understanding many human diseases.

Disease

Disease is a harmful pathologic consequence of infection. In many cases, infection is apparently harmless to the host and does not result in disease. One of the most important goals of pathogenesis research is to define in molecular terms what determines the difference between infection and disease. Even highly virulent viruses often establish infection in a greater

number of hosts than they cause disease. Viruses such as rabies, Ebola, or HIV, which cause significant disease in nearly all infected persons, are the exception.

Disease may be associated with cell and tissue destruction (as in rabies virus killing neurons), induction or secretion of inflammatory cytokines (as in the induction of fever by many viruses), cellular dysfunction induced by viral infection (as in the case with lymphocytic choriomeningitis virus [LCMV] infection of the pituitary), paracrine effects of viral gene products (as in induction of angiogenesis by Kaposi's sarcoma herpesvirus [KSHV]), and the induction of malignant tumors to the effects of the immune system as it responds to infection (as in immunopathology seen with many viruses) or to the presence of a specific virus interacting with allelic polymorphisms in the host to trigger disease.^{40,300}

In many cases, virus-associated disease is defined as a series of nonspecific symptoms or signs such as fever, malaise, or anorexia. The presence of these symptoms and signs is common to infection with many different pathogens and therefore provides little insight into the mechanisms of viral pathogenesis. Recent work with microarray technology suggests that even the nonspecific syndromes associated with acute virus infection with different viruses may be distinguished by the pattern of host gene expression. It is likely that pathogenesis researchers will use such molecular signatures to distinguish between infections with different viruses and to define host genes involved in viral pathogenesis.

In contrast to the nonspecific syndromes commonly associated with virus infection, the presence of specific symptoms or signs of disease such as hepatitis, immunodeficiency, pox on the skin, or paralysis provides important clues as to the nature of the pathogenic process. It is this relationship between the signs and symptoms of disease and the presence of infection with specific viruses that has led to the close link between clinical observations of the natural history of disease and the science of viral pathogenesis.

Virulence

Virulence—the relative capacity of a virus to cause disease—determines the relationship between infection and disease. Virulent viruses cause disease in a greater proportion of infected hosts, and cause more severe disease, than viruses of lower virulence. Virulence comes in many forms, from the induction of rapid death as for variola major (the causative agent in smallpox) to the induction of tumors over prolonged periods, as is the case with certain papillomaviruses or herpesviruses, to the induction of organ failure over many years, as is the case with chronic HBV or HCV infection. Thus, the manifestations of virulence highly depend on the strategies that a given virus uses during infection.

The determination of whether one virus (e.g., Ebola virus) is more virulent than another virus (e.g., papillomavirus) represents a qualitative judgment, because it involves determining whether virus-induced hemorrhagic fever (as is seen with Ebola virus) is worse than metastatic cancer (as is seen with papillomaviruses). To avoid biases inherent in comparing different types of disease, virulence is properly used to compare the disease-inducing capacity of related viruses, such as different strains of the same virus. For example, Ebola Reston, which is not associated with human disease, is less virulent in humans than Ebola Zaire.

It is commonly assumed that viruses that replicate efficiently in the host are more virulent than viruses that replicate less efficiently, and indeed replication is an important determinant of the severity of disease in many cases. However, virulence is much more complex than simply the efficacy of replication. Other aspects of pathogenesis, including tropism, the host response to infection, and interactions between the virus and host tissues, play key roles in viral virulence. Therefore, virulence reflects host resistance to infection functioning in counterpoint to viral virulence genes and determinants with the outcome for the host hanging in the balance.

Invasiveness

Invasiveness is the capacity of a virus to enter into and damage a tissue, a property that distinguishes viruses with high potential virulence but differ in the efficiency with which they enter target tissues. For example, a virus may be highly virulent if directly inoculated into the central nervous system (CNS) but unable to cause disease if inoculated into the periphery, whereas a related virus with a mutation allowing it to cross the blood–brain barrier into the CNS can cause lethal disease following either peripheral or intracranial inoculation. This concept is nicely exemplified by the identification of neuroinvasiveness determinants in Sindbis virus that confer the capacity to cause lethal encephalitis.⁶⁶

Cell-Intrinsic Versus Cell-Extrinsic Mechanisms

Because infected cells live in a tissue in the host, they are affected both by events that occur inside the cell and by events that influence the cell from the outside. Events that occur in a cell independent of events outside of the infected cell are termed *cell intrinsic*. Some cell-intrinsic determinants of infection are owing to intrinsic cellular resistance to infection conferred by the presence of molecules that block viral infection. Events that are dictated by processes that occur outside of the cell are termed *cell extrinsic*. Many cell-extrinsic events are owing to innate and adaptive immunity. It is often the case that processes occurring in infected cells or tissues are affected by both cell-intrinsic and cell-extrinsic mechanisms. An example is the induction of death of infected cells that may be owing to cell-intrinsic induction of programmed cell death or cell-extrinsic immune factors such as cytokines or perforin and granzymes.

Evasion of Host Molecules and Mechanisms

Most viruses have evolved mechanisms to counter host innate and adaptive immunity or to bypass intrinsic cellular resistance molecules so that the virus can complete the infectious process and spread to a new host. These mechanisms constitute viral *evasion* of host responses. Often, evasion strategies involve viral genes with close homology to host genes, as when a virus encodes a host cytokine or cytokine receptor mimic. Other evasion strategies utilize molecules with novel structures to avoid host responses. Because the mechanisms responsible for acute and chronic infection differ, both with regard to viral and host factors, it follows that immune evasion mechanisms are different for acute versus chronic infection. During acute infection, viral immune evasion strategies commonly focus on the host innate immune response, whereas evasion of adaptive immunity is more important for maintaining chronic infection. When analyzing immune evasion mechanisms, it is therefore

important to identify the aspects of the infectious process for which a given molecule is important.

Subversion of Host Molecules and Mechanisms

Viruses must be able to utilize host metabolic and regulatory systems to optimize their growth, survival, and spread. In some cases, the normal functions of the host cell may be sufficient for the virus to replicate. In other cases, host cellular processes may be insufficient or have deleterious effects on the virus. *Subversion* refers to the ability of a virus to redirect or alter normal host processes to the advantage of the virus. For example, some viruses subvert the function of chemokine receptors or other immune-signaling proteins to supply intracellular signals that regulate viral gene expression or encode molecules that subvert the cyclin-dependent progression of cell cycle. There are many different signaling pathways and cellular processes that are subverted by viruses; in fact, it is reasonable to presume that essentially every pathway and process within the cell is subverted by one virus or another. This is the inevitable consequence of the obligate intracellular lifestyle of viruses and their capacity to evolve more rapidly than the mammalian host.

Tropism

Tropism is the capacity of a virus to infect or damage specific cells, tissues, or species. It is a fundamentally important contributor to viral pathogenesis and virulence, as the capacity to induce disease depends on the cell and tissue infected. For example, a neurotropic virus such as West Nile Virus can cause encephalitis or paralysis, whereas a virus with tropism for CD4 T cells such as HIV causes immunodeficiency.

One key determinant of viral tropism is the cognate interaction between the viral cell attachment protein(s) and receptor(s) present on host cells. However, there are many additional factors that determine cell, tissue, and species tropism. The concept of tropism is rapidly evolving with the recognition that essentially every aspect of the viral infectious process within a cell or tissue can be a determinant of tropism. Both cell-intrinsic and cell-extrinsic factors may alter viral tropism.

Essential Genes, Virulence Genes, and Virulence Determinants

Virulence is determined by the capacity of a virus to grow, be invasive, infect vulnerable cells, evade the immune system, subvert cellular processes, and cause tissue damage. These capacities are encoded in the viral genome, by alleles of individual *virulence genes*. That viral genotype confers pathogenic capacity was proven by studies using reassortant viruses, mutant viruses, or molecularly cloned viruses to show that alterations in genotype confer virulence phenotype (e.g., 10,55,56,66,69,121,168,229,265,287,291,308). Subsequent studies have shown that different viral genes can confer capacities for infection in different tissues, indicating that viral virulence genes are tissue specific.^{109,175} Consistent with this, viral variants that arise during chronic infection are often cell and tissue specific.^{2,3,108,143,189}

Any gene essential for replication contributes to virulence, because viruses must replicate to complete their life cycle. In this sense, all viral genes involved in replication are virulence genes. As this is not a very useful concept, viral genes essential for replication in permissive cells are termed *essential genes* rather than virulence genes. Virulence genes are not required for replication *per se* but are important for virulence in the

host. Although the distinction between an essential gene and a virulence gene is useful, it is important to recognize that allelic variations in the function of essential genes can be important determinants of viral virulence. In this case, the specific property associated with virulence is termed a *virulence determinant*. Thus, virulence determinants can be allelic variants of essential genes that confer significant differences in pathogenesis.

The size of the viral genome puts boundaries on the number of genes that a virus can use for pathogenesis and replication. For example, smaller RNA viruses often have genomes of less than 10,000 nucleotides, whereas poxviruses or herpesviruses may have genomes greater than 200,000 nucleotides in length. However, viral proteins often have multiple independent functions—a property particularly well documented for RNA viruses. Thus, the pathogenic capacity of a virus with a small genome should not be underestimated.

Virus particles can contain virulence determinants that are not encoded in their genomes. For example, vaccinia virus incorporates host complement regulatory proteins into its envelope, thereby becoming resistant to inactivation by host complement proteins.²⁹⁴ Another type of epigenetic mechanism is exemplified by herpesviruses such as human cytomegalovirus (HCMV) and HSV that can package host and viral messenger RNAs (mRNAs) into the virion.^{36,93,251,282} Although their role in pathogenesis is not yet clearly defined, carryover of these mRNAs can result in synthesis of viral proteins before the traditional transcription program of the virus is initiated.^{251,282}

It is not necessarily true that viral virulence determinants exert their effects in host cells actually infected by the virus. One example of this is paracrine regulation of tissue pathology by virus-encoded cytokines. Another example is the movement of viral proteins from an infected to an uninfected cell. For example, the HSV protein VP22 can efficiently move from an infected cell to the nucleus of uninfected cells,⁶⁸ can carry other proteins between cells,²²⁴ and can transport mRNAs from one cell to the next.²⁵¹ This is a fascinating example of how a viral virulence determinant can act on uninfected cells to contribute to viral pathogenesis.

Virulence Genes and Determinants May Not Encode Proteins

Virulence can be conferred by viral promoters or other cis elements in the viral genome or noncoding RNAs. For example, EBV infection is associated with the development of B-cell lymphomas. The EBV EBNA1 protein plays an important role in the maintenance of latent EBV infection in B lymphocytes. EBNA1 can be expressed from any of four promoters—Cp, Wp, Fp, and Qp—each of which is regulated in distinct ways by viral and host proteins,²⁶⁴ ensuring that EBNA1 is expressed at the appropriate place and time in B cells. These finely tuned promoters are therefore properly considered virulence determinants for EBV-associated malignancies. Another example of non-protein-coding virulence determinants are virally encoded microRNAs, which are expressed by a number of mammalian viruses, including herpesviruses, adenoviruses, and polyomaviruses.^{228,257} These noncoding RNAs target multiple cellular processes, including cell cycle regulators, apoptotic machinery, or virus-encoded transcript, and play a role in promoting viral persistence. Noncoding elements also play important roles in the pathogenesis of several RNA viruses. For example, attenuating mutations within the internal ribosomal entry site

(IRES) of the Sabin vaccine strain of poliovirus are important for replication in neurons and neurovirulence in mice and primates.^{97,99,141,149} It is becoming increasingly clear that the transcriptional complexity of a broad range of organisms is considerably higher than previously believed,^{23,117} and it is now recognized that this is also the case for viruses such as herpesviruses.^{46,47,133} It is likely that virulence genes that do not encode proteins will increasingly be recognized in many viruses.

CONCEPTUALIZING VIRAL PATHOGENESIS

Every fact or principle presented in this textbook relates in some way to the pathogenesis of infection or disease. Thus, it may seem that pathogenesis is too complex to be studied in any mechanistic detail, or that viruses differ so significantly that common principles do not exist. This problem is further compounded because many events and processes are going on at the same time *in vivo*. Furthermore, processes that occur *in vivo* are nonlinear (e.g., unrestricted viral replication may be exponential) or even stochastic (e.g., whether a mutation occurs when a genome is replicated), or otherwise are the results of as-yet-unidentified allelic variations in host genes that influence pathogenesis.^{1,300}

Given this complexity, it is worth considering how the questions of pathogenesis are formulated and placed in context for interpretation. There are many ways to look at infection—three of which are presented here as a basis for understanding viral pathogenesis. Pathogenesis may be conceptualized as an organized process consisting of sequential stages, as the result of stochastic events under selection by bottlenecks in infection, or as the integration of host allelic variations in genes that determine resistance to infection. Each view of pathogenesis has its limitations and benefits as a basis for understanding the nature and mechanisms of viral infection.

Clinical Observations Define Fundamental Pathogenesis Questions

Viral pathogenesis has been studied for longer than any other aspect of virology; however, in many ways, we know less about pathogenesis than we do about other aspects of virology. The pathogenesis of viral disease was studied before viruses were even identified. Smallpox was known before variola virus was identified, and rabies virus was propagated in animals and an effective vaccine was developed by Pasteur before the virus was characterized.¹³¹ It was known that chickenpox infection conferred lifelong resistance to disease before varicella-zoster virus (VZV) was identified. A study of measles in 1886 in the Faroe Islands identified the incubation period between exposure and disease, resistance of previously exposed individuals to reinfection, and the susceptibility of the very young to disease.^{95,96} These clinical observations often identify the questions that must be answered in pathogenesis studies. For example, mosquito-borne alphaviruses such as chikungunya virus cause severe acute and persistent arthralgia in infected humans, raising the question of how these viruses cause joint pain and whether chronic disease is associated with viral persistence. Through the careful analysis of human clinical samples and the use of appropriate animal models, the viral pathogenesis researcher can begin to define the molecular mechanisms underlying a disease process.

Conceptualizing Viral Pathogenesis as a Series of Sequential Stages in Infection

A very useful way to conceptualize viral pathogenesis is as a series of sequential stages resulting in survival and spread of a virus through the infected host and on to a new host (Figs. 10.2 and 10.3). Different viruses may utilize distinct molecular

mechanisms to accomplish each of these stages. For example, all viruses must infect cells on entry into the host and must spread to new hosts. As the host has mechanisms to inhibit each of these stages of infection, the stages of infection may be considered as hurdles over which the virus must jump to survive.

There may be more than one way for a virus to overcome such a hurdle; however, different viruses may utilize the same strategy to overcome a given hurdle. An example of a common strategy is the relative resistance of some viruses to inactivation in water or sewage, allowing them to spread between hosts by fecal–oral transmission. Another example is infection of the thymus resulting in deletion of virus-specific T cells as *self*-antigens. Yet another common strategy is evading immunity via the establishment of latent infection. Thus, there are many common strategies for infection shared by different viruses.

Dividing viral pathogenesis into stages is a very useful way to conceptualize the infectious process but has significant limitations. First, dividing pathogenesis into stages creates the impression that events are both sequential and depend on each other. This is not always the case; many independent events may be going on at the same time in the host. Second, this conceptual framework suggests that completion of a stage is associated with initiation of the next stage; a significant oversimplification. For example, viremia may continue after a virus has entered the CNS to cause encephalitis. The utility of considering viral pathogenesis as a series of sequential events must be balanced against how well this conceptual framework fits actual events during infection.

Poliovirus pathogenesis provides an excellent example of how pathogenesis can be broken down into a series of steps that culminate in either virus-induced disease or viral control. Clinical questions that drove poliovirus pathogenesis research through the first half of the past century included why poliomyelitis emerged in the 20th century, what mechanisms were responsible for paralysis, and how did protective immunity work.^{183,234,235,274} Solving these questions was central to combating a very important and pressing public health problem. Infection with poliovirus in humans has a wide range of possible outcomes from asymptomatic infection to meningoencephalitis with or without paralysis.^{183,234,235,274}

Studies over many years identified and analyzed a series of stages of poliovirus infection, leading to a relatively simple model for the pathogenesis of disease that elegantly explains paralysis, the low proportion of infected hosts paralyzed, and the lifelong immunity conferred by prior infection. This model, one of the most useful ever constructed, provided a basis for developing the poliovirus vaccines that have largely, although not completely, eliminated paralytic poliomyelitis as a scourge of humanity.

The stages in poliovirus pathogenesis according to this model are outlined in Figure 10.2.^{24,183,234,235} The virus enters the intestine via the fecal–oral route, binds to M cells overlying the Peyer's patch, is transported into the intestinal wall, and then replicates in lymphoid cells, leading to a primary viremia and infection of secondary sites. Replication in secondary sites gives rise to a secondary viremia that reaches a level capable of initiating CNS infection.^{234,235} CNS infection involves passage of the virus across the blood–brain barrier to infect neurons within the CNS. The blood–brain barrier is viewed as an

FIGURE 10.2. Model of poliovirus pathogenesis as a series of sequential stages. The steps in poliovirus infection of a human are schematized.

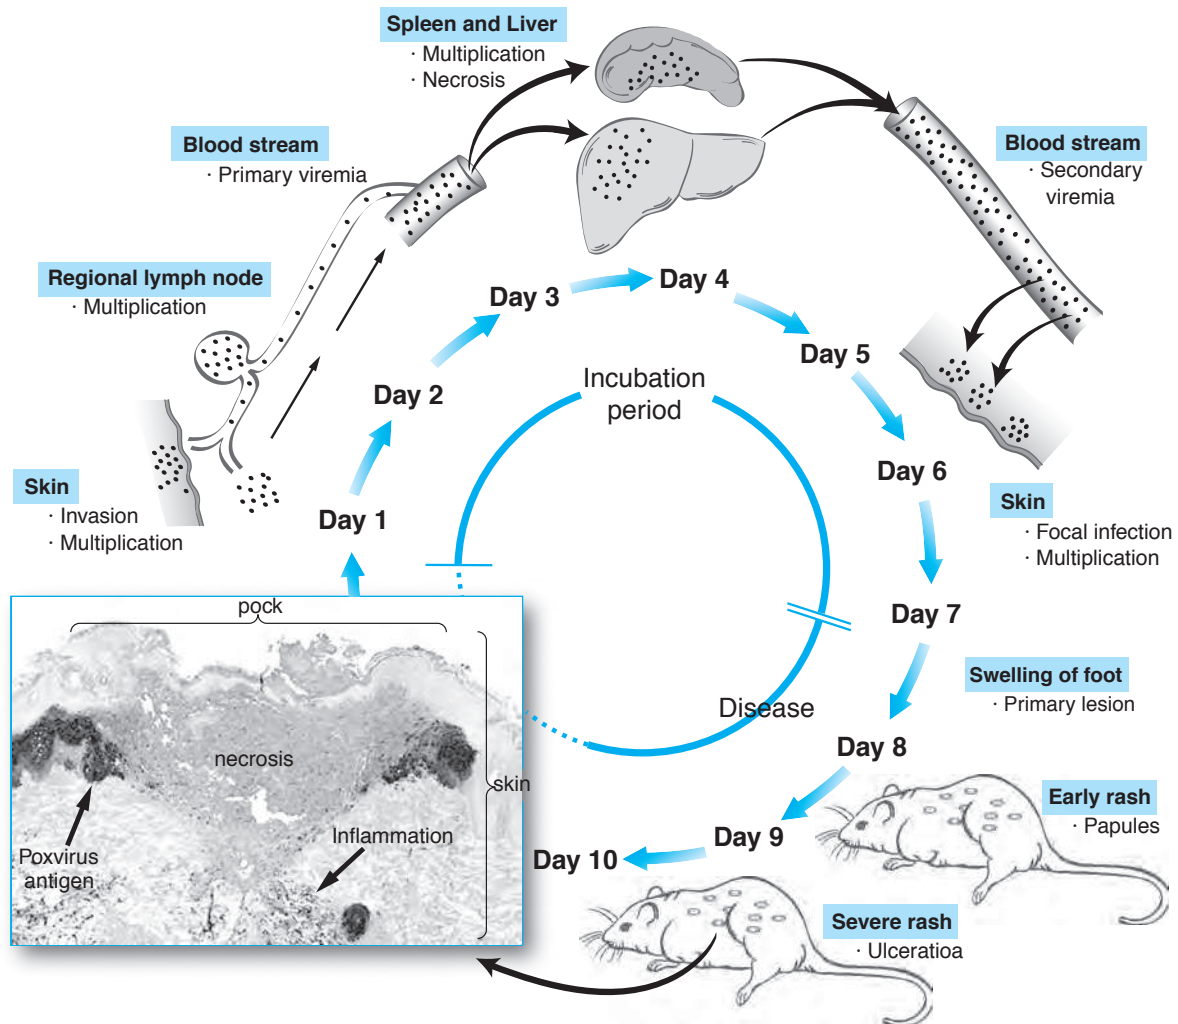

FIGURE 10.3. Model of poxvirus pathogenesis as a series of sequential stages. The steps in ectromelia virus pathogenesis are schematized. The outcome of ectromelia infection varies with mouse and viral strain.^{39,75} The viremia is thought to be cell associated. The histopathologic image of a pock was provided by Drs. Mark Martinez and Peter Jahrling and is skin from a variola-infected monkey stained with specific antisera to identify the infected cells shown as *poxvirus antigen* in the inset image. (Adapted from Fenner F, Buller RM. Mousepox. In: Nathanson N, Ahmed R, Gonzalez-Scarano F, et al, eds. *Viral Pathogenesis*. Philadelphia: Lippincott-Raven, 1997:535–553.)

important anatomic barrier to infection of the CNS, and passage across this barrier is poorly understood. Alternatively, the virus may spread via the blood to peripheral nerves and then spread up the nerves to enter the CNS.^{98,185,205,235,241} Within the CNS, the virus infects motor neurons; destruction of these cells leads to paralysis. Certain motor neurons are hypothesized to be more susceptible to poliovirus infection than others, and some poliovirus strains are either more invasive or more likely to kill neurons than others; these variables contribute to variation in disease penetrance and severity.

Concurrent with entry into the lymphatic system, an immune response is generated (see Fig. 10.2). It is hypothesized in this model that immune antibody limits access to the CNS and prevents paralytic disease.^{183,235} Antibody might act by preventing virus in the circulation from crossing the blood–brain barrier and entering the CNS. However, antibody is capable of inhibiting neural spread of viruses and can

inhibit viral infection by acting directly on or within neurons.^{160,183,290,292,299} Regardless of the mechanisms by which antibody protects, the outcome of infection is a race between the virus and the immune system, presenting another explanation for variations in clinical outcome. The immune system wins if antibody is made early enough to prevent spread to the CNS and neuronal destruction. The virus wins if infection of motor neurons occurs prior to development of protective antibody responses.

This model provides a basis for understanding many aspects of poliovirus infection, disease, immunity, and vaccination; however, many questions are left open. Questions that remain unanswered at the molecular level include how the virus enters the body, the molecular basis of cell and tissue tropism, the mechanism by which antibody acts to prevent CNS disease, the mechanisms of induction of immunity, and the route(s) by which the virus spreads.

Importantly, although the mechanistic details underpinning the pathogenesis of different viruses will differ significantly, the broad stages of the systemic infection process outlined for poliovirus pathogenesis are also relevant for a wide array of other viral pathogens. For example, although poxviruses are very different from small RNA viruses, such as poliovirus, there are remarkable parallels between the models of poliovirus infection (see Fig. 10.2) and those for poxviruses (Fig. 10.3). This includes the concept that both viruses must reach a threshold of viremia to facilitate viral invasion into target organs and that the disease process represents a race between the virus and the host immune response, where the outcome of that race plays a major role in determining whether the virus is controlled or if disease results. Refer to the eBook for a more complete description of poxvirus pathogenesis as a stepwise process. These general principles extend to a wide array of viral pathogens, including arboviruses, herpesviruses, and lentiviruses.

Conceptualizing Viral Pathogenesis as the Interaction Between Stochastic Events and Bottlenecks in Infection

It is important to recognize that the process of infection has, in addition to a series of predictable events that occur in sequence, an element of stochastic variation that contributes to real variability to the outcome of infection. Thus, viral pathogenesis can be conceptualized as a series of stochastic events with the process of infection determined by strong selective pressures in the host referred to as bottlenecks in infection (Fig. 10.4). These bottlenecks can be thought of as analogous to the rate-limiting step in a chemical reaction. Stochastic events such as mutations or the random success of a given virus at a stage in infection provide variation in the substrates for these rate-limiting steps.

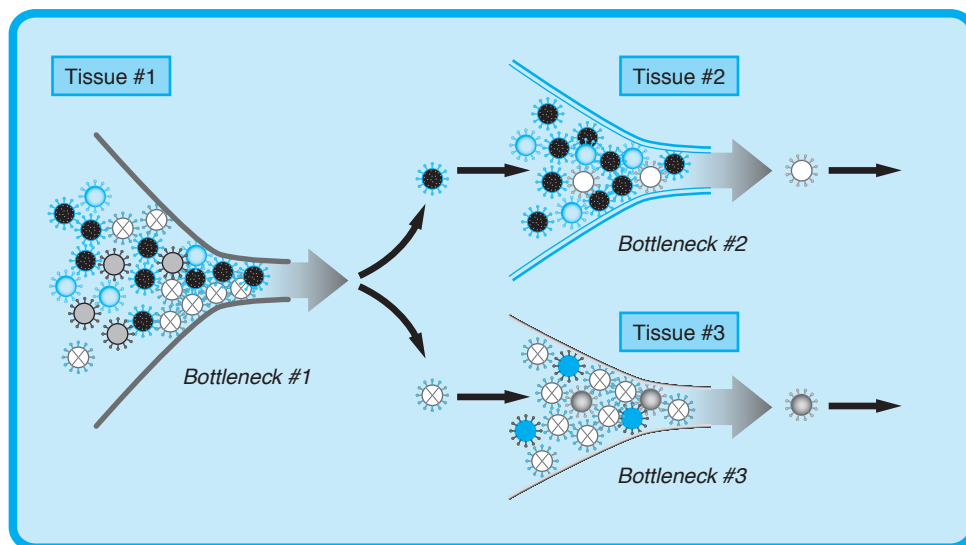

The concept that random events contribute to pathogenesis is not a comfortable one for investigators. However, even using clonal virus stocks for inoculation of genetically identical mice of the same sex and age results in viral titers in tissues that vary considerably (even by orders of magnitude) from one mouse to the next. This variation is not experimental error or noise but is rather a real phenomenon relevant to understanding infection. During natural infection of genetically variable

hosts with viral quasispecies, the variation is likely to be much larger.²⁹⁷

The reasons for the occurrence of significant variations even when conditions of infection are apparently homogeneous are not clear but likely involve several different factors, including epigenetic changes within the host, specific interactions between viruses and certain host genes that confer disease,^{44,300} environmental variables, and viral factors such as viral mutation rates that drive the generation of mutants with selective advantages in the host. This latter process, which involves the random generation of mutant viruses—a subset of which may provide a selective advantage that allow the virus to overcome bottlenecks and efficiently spread throughout the host—represents an important component of viral pathogenesis. For example, polioviruses that have high-fidelity polymerases, and therefore are less able to generate mutant viruses, are less efficient in infecting target tissues and causing disease, suggesting that the generation of viral quasispecies allows the virus to overcome bottlenecks and is essential for disease pathogenesis.²⁹⁶

Selective pressures at bottlenecks in infection can select mutants from within the viral quasispecies that have a fitness advantage (see Fig. 10.4). This is illustrated experimentally by studies with Venezuelan equine encephalitis virus (VEE), an equine pathogen that infects both humans and mice. Following subcutaneous inoculation, VEE initially replicates in the draining lymph node before seeding a serum viremia that leads to viral dissemination and ultimately viral entry into the CNS. Studies that compared molecularly clones of wild-type VEE to a mutant virus with a defined mutation at position 76 in the E2 envelope protein demonstrated that the mutant virus replicated within the draining lymph node but failed to spread systemically. Importantly, infection with the mutant virus led to the rapid generation of viruses that were able to efficiently spread within the host, and characterization of these viruses found that some contained a reversion of the original E2 mutation to wild-type. However, other viruses maintained the original E2 mutation but developed second site mutations that conferred the ability to disseminate systemically.^{10,94} These results demonstrate that there may be many ways to overcome

FIGURE 10.4. Viral pathogenesis as stochastic events followed by selection by bottlenecks in infection. Shown is a representation of a viral quasispecies, only two of which are fit to pass through an initial bottleneck in infection. Subsequent replication of these viruses in different tissues generates further quasispecies that are again acted in by selective forces at further bottlenecks in infection.

a specific bottleneck. Bottlenecks may also be responsible for significant variations in the kinetics of infection between hosts. For example, a variant capable of bypassing a given bottleneck may arise sooner in one host than in another. Refer to the eBook for an expanded discussion of how VEE rapidly mutates to overcome bottlenecks in infection.

An example of a bottleneck in infection exerting a selective pressure comes from HIV infection. When an infected person exposes an uninfected person to the diverse HIV quasiespecies that develops during chronic infection, the viruses that emerge in the new host represents only a subset of the viruses in the inoculum.^{106,301} This suggests the existence of a bottleneck early in infection through which some viruses selectively pass. Detailed study shows that HIV viruses that utilize the CCR5 co-receptor are more efficient at spread and initial replication in both men and women than viruses that utilize CXCR4 as a co-receptor.^{167,214,231} This suggests that co-receptor utilization is a critical event for passing through a bottleneck during the initial stages of infection. After passage through this bottleneck, HIV isolates that utilize CCR5 are less fit for later events in infection leading to selection of viruses utilizing CXCR4 as a co-receptor. Thus, a virus that is more effective at passing one bottleneck in infection can be replaced, via mutation and selection, by viruses more fit for bypassing subsequent bottlenecks in infection. For these reasons, one must not assume that the virus initially entering the host is the virus responsible for viral disease but must consider stochastic events and selective pressures in models of pathogenesis.

An important consequence of passage through a bottleneck is contraction of quasiespecies heterogeneity. When a mutant virus is selected, allelic variations in regions of the genome that are not under selective pressure are carried along through the bottleneck. Thus, random mutation followed by selection can generate novel viruses with properties that are not selected for at all and may therefore have unique pathogenic properties. For example, a virus may mutate sequences encoding a T-cell epitope to escape control by T lymphocytes, and this new sequence may confer previously unexpected properties to the virus. Therefore, selective pressure may result in the emergence of different viruses in different hosts, providing a

mechanism for the emergence of viruses with new properties in a population of susceptible individuals.

Conceptualizing Viral Pathogenesis as the Integrated Effects of Host Genetic Variation

The previously discussed ways to conceptualize viral pathogenesis are highly focused on the virus, but it has been clear since the earliest studies of viral pathogenesis that hosts differ significantly in genetic susceptibility to infection.^{44,301} The major host determinant of viral virulence and pathogenesis is innate and adaptive immunity, but host genes not involved in immunity also play a role. Allelic variations in these host genes can alter viral pathogenesis (Fig. 10.5).

The extent to which allelic variations in host genes control viral pathogenesis is only now being appreciated. Some examples are well established, whereas others come from single studies and await confirmation. Mutations in CCR5 confer resistance to HIV infection.^{57,164,248} Human noroviruses (type virus Norwalk) are responsible for more than 90% of the epidemic nonbacterial gastroenteritis in the world.^{61,90} Norwalk virus susceptibility is determined by blood group secretor status conferred by the presence of the FUT2 fucosyltransferase.^{127,163} Among human norovirus strains, there are multiple patterns of virus-like particle (VLP) binding to blood group carbohydrates, suggesting that allelic variation in human blood groups contribute to susceptibility to a variety of norovirus strains. Patients with mutations in the IFN γ receptor have been reported to have unusual viral syndromes.²²⁶ Autosomal dominant mutations in the chemokine receptor CXCR4 have been associated with severe warts,¹⁵⁴ and mutations in *EVER1* and *EVER2* have been associated with an unusual clinical presentation of papillomavirus infection called *epidermodysplasia verruciformis*.²³⁷ Allelic variations in mannose-binding lectin and Fc γ RIIA have been linked to the severity of severe acute respiratory syndrome (SARS).^{130,320} A relationship between expression of certain KIR genes, encoding NK cell receptors, and severity and chronicity of infection with HIV, HCV, and EBV have been reported.⁴³ Responsiveness to hepatitis B vaccine may be linked to allelic variations in complement genes.^{25,119} Thus, a significant number of allelic variations in

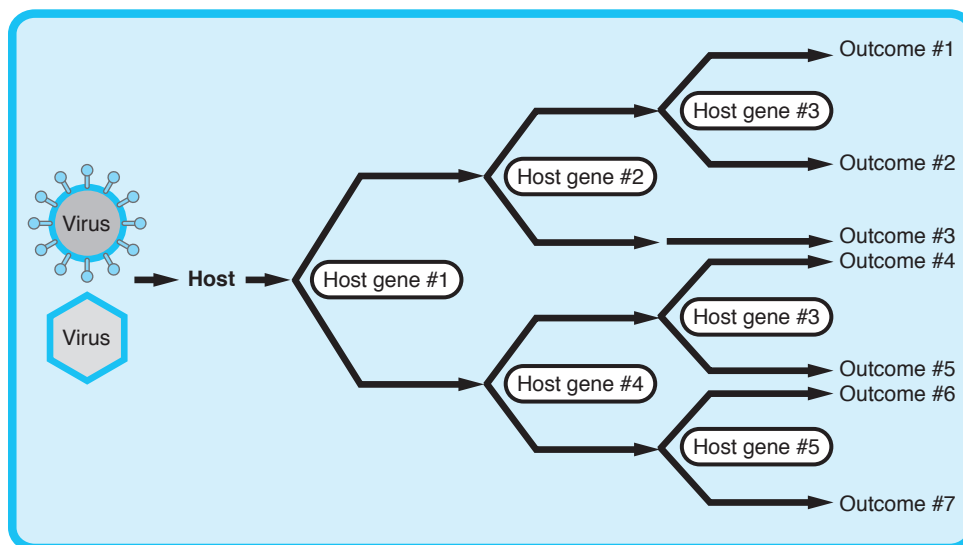

FIGURE 10.5. Viral pathogenesis as the result of the action of a series of host genes. Shown is a representation of infection with different viruses progressing through the host as acted on by host genes that confer either resistance or susceptibility to infection. Depending on the effects of host gene 1, one of two different patterns of infection emerges. In turn, additional host genes interact with the virus, resulting in different outcomes for the host. Note that the more host genes play a determining role, the greater the number of possible outcomes.

humans are important determinants of viral pathogenesis, and additional candidates for such variation are being found at a high rate. Refer to the eBook for further discussion of how variation in blood group secretor status affects susceptibility to human norovirus infection.

Although many studies have focused on the impact of variation in a single gene on viral susceptibility, it is clear that susceptibility or resistance to viral infections is a complex phenotype regulated by multiple interacting genes and gene networks. For example, studies designed to identify genes that regulate resistance to influenza infection between two mouse strains have identified multiple quantitative trait loci (QTL) that contribute to disease susceptibility.²⁸ Although the full number of host genes that vary between susceptible and resistant hosts for a single virus is only beginning to be understood, it is likely that variation in hundreds of different genes may contribute to disease resistance or susceptibility.^{44,302} Recent advances in the area of host genetics, including the application of genome-wide association studies (GWAS), which scan the genome for allelic variants, such as single nucleotide polymorphisms (SNPs), associated with specific phenotypes, as well as whole exome and whole genome sequencing, promise to further enhance our understanding of how different polymorphic genes contribute to disease susceptibility. For example, recent application of GWAS approaches to identify genes that associate with HIV control identified a major association between polymorphisms in the human leukocyte antigen (HLA) locus that affect class I peptide presentation to CD8 T cells and an individual's ability to control HIV.²²¹ These approaches have also been extended to HCV and recently identified a polymorphism within the *IL28B* gene (interferon λ 3) that associates with viral clearance following therapy with interferon.⁸⁴ These types of findings have direct implications for predicting treatment outcomes for infection in patient populations, as has been suggested for inflammatory diseases.³⁰⁰

The examples outlined previously illustrate that allelic variants in host genes can have a significant impact on the pathogenesis of infection (see Fig. 10.5). As multiple independently segregating genes contribute to the susceptibility or resistance to a viral pathogen, many human genotypes exist that may vary significantly in their resistance to even a single viral infection. Therefore, even without considering the impact of viral virulence determinants or other environmental factors, much of the variation in viral pathogenesis within a diverse population could be explained by polymorphisms in host genes. This has implications not only for viral pathogenesis in human populations but also for studying viral pathogenesis in animal models. Although GWAS and candidate gene studies in humans can establish an association between a polymorphic gene and susceptibility to a viral infection, the investigation of the mechanisms by which a polymorphic gene or genes affects pathogenesis requires additional tools, including appropriate animal models. However, pathogenesis studies are often performed in genetically homogeneous experimental hosts (e.g., inbred mouse strains), which results in the loss of any significant effect of host genetic variation on viral pathogenesis and limits investigation of how allelic variants affect pathogenesis outcomes. New model systems that more accurately model the genetic diversity that is present in human populations, such as the Collaborative Cross mouse RI panel,¹¹ as well as classical mouse genetics systems, including BXD recombinant inbred

lines,²⁸ should enhance studies of the role of host variation and gene:gene interactions in viral pathogenesis.

THE STUDY OF VIRAL PATHOGENESIS

Many different tools must be used to understand the complex process of viral pathogenesis. Some of these tools have played essential roles in understanding pathogenesis and will continue to be useful. Examples include assays for infectious virus and histopathologic evaluation of infected tissues. Others are more recently developed and have only been applied in limited circumstances. Understanding the tools of experimental pathogenesis research is essential to understanding the interpretation of experiments that have contributed to our current understanding of virus infection.

Epidemiology

Epidemiology is an essential tool for pathogenesis research for defining patterns of disease and infection and the mode of transmission between hosts. Together with assays for prior infection such as serology or molecular detection of chronic virus infection, epidemiology can define the relationship between infection, immunity, and disease. Epidemiologic studies link a virus to a specific disease and allow formulation of the fundamental questions that must be answered to understand viral pathogenesis. This is nicely illustrated by the identification of Kaposi's sarcoma (KS) herpesvirus, where epidemiology studies suggested that HIV status alone was not an accurate predictor of KS risk, indicating that an additional co-factor was responsible for KS.^{48,250} Following the discovery of KSHV,⁴⁸ additional epidemiologic investigations convincingly linked KSHV infection with KS via demonstration that KSHV sequences were present almost universally in KS lesions and that seroconversion to KSHV preceded the development of KS.¹⁷⁴

In some cases, epidemiologic investigation finds that known viruses explain but a part of the disease burden, leaving open the question of whether unknown agents contribute to disease. The process of associating new viruses with both viral and nonviral diseases continues to this day, with new viruses constantly emerging or being identified as responsible for already described diseases.

Animal Models

Animal models are fundamentally important tools for the study of viral pathogenesis. The need to understand human infection, combined with the complexities of doing human studies, has led to the use of animal models to ask pathogenesis questions that cannot be effectively answered via human studies. There are two types of animal models for human viral disease. In the first, one studies a human virus in infected animals. In the second, one studies an animal virus that is related to a human virus in its animal host. There is an essential tension between these two approaches; in one the "real" pathogen is studied, and in the other a "natural" infection is studied. In truth, each has its advantages and each its limitations.

Study of Human Viruses in Animal Models

Human viruses can be studied in animals that are susceptible to infection either because the virus does not exhibit species tropism or because tropism restrictions are overcome via genetic

manipulation of the host or virus. An important caveat of such studies is that human viruses seldom or never behave in an experimental animal exactly as they do in humans. Nevertheless, this is a very valuable approach. Examples include the use of mice to study HSV, Sindbis virus, yellow fever virus, VEE, LCMV, or chikungunya viruses; the use of humanized mouse models to study HCV and HIV; and the use of primates to study poliovirus, variola, HIV, and Ebola virus.

Excellent examples of this approach are the analysis of infection with filoviruses such as Ebola or Marburg that are very difficult to study in infected patients. However, these viruses cause disease in macaques with significant similarities to human disease, including a striking hemorrhagic diathesis including disseminated intravascular coagulation.^{85–87} These animal models have been used to demonstrate that it is possible to vaccinate against filovirus infection^{136,270,319} and that passive transfer of antibody can be partially protective.^{105,216}

Not all human viruses can replicate in animals. Five approaches have been taken to overcome this hurdle. These approaches are, first, passage-based adaptation of the human virus to growth in an experimental animal; second, engineering of the host to accommodate all or part of the pathogenesis of the human infection; third, expressing the virus as a transgene in an experimental animal; fourth, the creation of humanized mice where immunodeficient mice are reconstituted with aspects of the human immune system and components of the human target organ (e.g., the liver for HCV); and fifth, targeted modification of viruses to allow replication in a model host. Increasing knowledge of the mechanisms of viral pathogenesis and immunity holds out great hope for generations of better animal models.

1. In the first approach, a human virus is adapted to growth in an animal model. Ebola has adapted to infect guinea pigs and mice.^{35,52,89} Ebola infection of small animals is similar to primate and human Ebola infections in some ways. For example, dendritic cells (DCs) and monocytes are early targets of infection in all of the different models. However, mice and guinea pigs do not show the hemorrhagic diathesis seen in humans and macaques, which is a significant limitation for pathogenesis studies.^{35,52,85,89}
2. In the second approach, the host is genetically engineered to allow analysis of a human virus. For example, transgenic expression of the poliovirus or measles virus receptors in mice confers susceptibility to intracerebral infection with poliovirus or measles virus.
3. In the third approach, the virus is expressed as a transgene in a live animal, allowing the replication cycle of the virus to proceed in certain cells even though the host is nonpermissive for infection. This has been accomplished for HBV with mice engineered to generate infectious virus from a transgenic viral genome.^{103,104}
4. In the fourth approach, mice are used as hosts for human tissue allografts that can then be infected with human viruses. This approach is particularly useful for viruses that fail to replicate in nonhuman systems and has been applied to viruses such as HIV¹⁵⁵ and VZV.^{14,249,321}
5. In the fifth approach, the virus is manipulated in a specific way to allow infection of the animal to be used as a model. For example, based on an intimate knowledge of the mechanisms of lentivirus species tropism, it has been possible via

manipulation of the HIV *vif* gene to create an HIV isolate that can replicate in macaques.¹¹³

Study of Animal Virus Infections That Resemble Human Infection

It is often impossible to approximate all aspects of the pathogenesis of a human virus in an animal model. An important alternative approach is to study the pathogenesis of an animal virus that is related to a human virus in an animal host. Examples include the study of murine cytomegalovirus (MCMV) as a model for HCMV, simian immunodeficiency virus (SIV) as a model for HIV, murine γ HV68 as a model for human γ -herpesvirus infection, myxoma virus and ectromelia virus as models for smallpox, and murine norovirus infection as a model for human noroviruses. These models provide, especially in the murine system, tools for doing pathogenesis and host genetics that are unavailable in any other model.

An important caveat of this approach is that animal viruses seldom faithfully reproduce in every detail of a human disease. This is not surprising; after all, animals are not humans and animal viruses are not identical to human viruses. These dissimilarities are often used to argue against the utility of such animal models. However, many principles and mechanisms of viral pathogenesis have first been described in animal models and later proven relevant in humans.

Viral Genetics as a Tool for Analysis of Pathogenesis

Studies taking advantage of genetic differences between viral strains are as old as the study of pathogenesis itself. Comparisons between viral strains can identify correlates of virulence or attenuation but do not necessarily shed light on the mechanisms responsible for the phenomena observed. Reliance on naturally occurring strains of virus has strict limitations for defining pathogenesis mechanisms, because it is only by luck that genetic variation occurs between strains in a manner that allows a specific hypothesis to be tested. Thus, advent of sequencing, structural biology, and directed mutagenesis of viral genomes as tools for pathogenesis research has been a turning point for pathogenesis as an experimental science. Infectious clone technology now exists for most virus families, and by applying directed mutagenesis strategies to these molecularly cloned viruses, mechanistic hypotheses can be tested directly. Often, this is done using a loss-of-function genetic approach in which an entire viral gene is deleted or in which a mutation is used to ablate a specific biochemical function of a viral protein. By evaluating such viruses, one can link structural and biochemical properties of a protein to specific aspects of pathogenesis, thus making loss-of-function genetic approaches a fundamental part of current pathogenesis research.

It is important to understand the limitations of viral mutagenesis as an approach. First, loss-of-function genetic analysis depends on whether a viral property can truly be attributed to a specific mutation. Further, it is necessary to prove that a phenotype is not an artifact of changes that occur during manipulation of the viral genome. This is often accomplished by *marker-rescue*, in which the mutant virus is repaired to wild-type status and the resulting virus characterized. If this marker-rescued virus is different from the wild-type virus, it indicates that other mutations have occurred during the process

of mutant generation, thereby invalidating conclusions drawn using the mutant. This can be particularly problematic for rapidly evolving RNA viruses that may select compensatory mutations during generation of viral stocks. An alternative is to fully sequence the viral mutant—an approach that is now increasingly practical for even the largest viruses.

It is also necessary to prove that a phenotype is owing to a change in a viral protein and not to alterations in cis-elements in the viral genome or in adjacent genes that may confer phenotypes. For example, mutating a residue in a protein might alter a promoter for another viral gene or change the processing of a viral polypeptide. These problems are addressed by studying multiple distinct mutations in a protein, analysis of the expression of other viral proteins, or, when possible, complementing the mutation by expressing the protein in trans from another location in the virus.

A second limitation of loss-of-function genetics is that linking a mutation in a virus to a specific alteration in pathogenesis shows that the gene in question is necessary but does not indicate that the gene is sufficient for the virus to perform a specific task. For example, several genes might be important for an aspect of pathogenesis such that mutation of any one of them would give a phenotype; however, no single gene is independently sufficient for the virus to perform a certain task *in vivo*.

A third limitation of loss-of-function genetics is that the identification of an important role for a gene at a given step in pathogenesis does not provide information on the mechanisms responsible for the phenotype observed. In the absence of additional studies, one can only make correlative statements about the relationship between the behavior of a mutant virus and the biochemical properties of the protein encoded by the altered gene. For example, if a certain amino acid is important for binding of a host protein by a viral protein, and that same mutation causes the virus to be defective in pathogenesis, it is plausible that the phenotype observed *in vivo* relates to the binding between the host and viral protein. Proof of mechanism *in vivo* requires additional studies.

Interactions Between Host and Viral Genes in the Study of Pathogenesis

Defining the mechanism of action of a viral protein or gene *in vivo* is much more complex than showing that the gene is important, requiring that one determine experimentally why pathogenesis is altered by a specific mutation. It is this latter level of analysis that provides the greatest challenges. The attribution of changes in pathogenesis to a specific biochemical property of either the host or the virus is a complex task. The most important question is whether a change in the behavior of a virus *in vivo* is attributable to direct effects of a given mutation or is owing to indirect effects of the mutation. To exemplify this problem, consider the case of a mutant virus that both grows more poorly and induces a lesser inflammatory response than the wild-type virus. One interpretation of such data might be that the mutation influences the function of a gene that evades or subverts the host inflammatory response. A more trivial interpretation is that the host responds to a virus that grows poorly with a lesser inflammatory response. In this situation, one cannot cleanly attribute an immune evasion property to the viral protein in the absence of additional data.

This problem is conceptually similar to the Heisenberg uncertainty principle in physics in which detecting an electron requires the use of a particle that in turn changes the location of the electron. Analogously, one determines the function of the viral gene by mutating the gene; however, mutating the gene can change the process of infection sufficiently to complicate interpretation of any differences observed in pathogenesis.²⁹⁷ A major challenge in defining mechanisms of viral pathogenesis is then to identify genetic, structural, and pathogenesis approaches that allow attribution of events *in vivo* to specific biochemical mechanisms.

One method for doing this involves using a combination of host and viral genetics in a process termed *host complementation*. For example, the *ICP34.5* gene of HSV is essential for viral virulence.^{27,50} One activity of ICP34.5 is to bind protein phosphatase 1A (PP1A) and to redirect PP1A phosphatase activity to dephosphorylation of eIF2 α , thereby reversing the eIF2 α -dependent antiviral effects of PKR.^{51,115,116,245,277} If ICP34.5 is acting to promote virulence through interactions with PKR, the ICP34.5 mutant should exhibit restored virulence specifically in mice lacking PKR, but not mice lacking other antiviral effector molecules. In fact, deletion of PKR, but not RNase L, from mice fully restores the virulence of an ICP34.5 mutant virus,¹⁵⁶ thereby establishing that ICP34.5 interacts with PKR *in vivo*. Other examples of this approach include the role of the influenza virus *NS1* gene in countering STAT-1 dependent innate immunity,⁸³ the role of the murine γ HV68 complement regulatory protein v-RCA in evasion of complement responses,¹³⁸ and the role of the *m157* gene of MCMV as natural killer (NK) cell-activating receptor ligand.^{9,78,260} In all of these studies, deletion of a host gene or cell type has been used to define the mechanisms of action of a viral gene during infection.

It is important to note that this approach is limited to analysis of host genes that do not play an essential role in development or the ontogeny of the animal or the immune system. Moreover, it is essential to use controls including a viral mutant that is unaffected by mutation of a host pathway and a host mutant in which the viral mutant maintains its attenuated phenotype. Simply showing that a mutant virus regains growth or virulence in an immunocompromised host does not constitute genetic proof that a viral gene is countering a specific host pathway.

An important correlate of these experiments is that one must interpret studies of wild-type viruses in animals lacking specific genes with caution. For example, if a mouse lacking a certain gene is capable of resisting infection normally, it is often concluded that the host gene is unimportant. An alternative interpretation is that the virus encodes a molecule that effectively inhibits the host pathway in question, making even a wild-type host effectively deficient in the pathway. The erroneous conclusion that a host pathway cannot play a role in infection has important consequences. For example, inhibiting the viral protein responsible for evading a protective host response might allow the host to effectively control infection. Thus, potential therapeutic approaches for viral infection may be missed by ignoring the possible presence of effective viral strategies for evading host responses.

Cell Culture

Cell culture is an essential tool for the study of viral replication and tropism. However, conditions in cell culture are not

representative of conditions *in vivo*, and thus hypotheses from cell culture experiments must be validated *in vivo*. One obvious limitation to cell culture studies is the absence of a cellular immune response. There are additional important limitations to cell culture studies. Often, a small proportion of cells in a tissue are actually infected at a given time, whereas cell culture is often optimized for synchronized infection of all cells. This obviates effects of infected cells on as-yet-uninfected cells—a fundamentally important part of what happens in tissues. For example, interferon released from one infected cell can protect uninfected cells from viral infection. As interferon effects generally require induction of gene expression, pretreatment of cells in culture is usually required to see full effects of interferon on viral infection, effects that are lost if all cells are simultaneously infected. Furthermore, cultured cells are often transformed or continuous lines whose behavior is at most distantly related to the behavior of primary cells. Even when primary cells are used in tissue culture, it is unlikely that the biology of these cells is the same as the biology of cells residing in a tissue in contact with physiologic extracellular matrix, the circulatory system, the endocrine system, and other primary cells.

DETERMINANTS OF CELL, ORGAN, AND TISSUE TROPISM

One of the most important concepts for understanding pathogenesis is the concept of cell, organ, and species tropism. Tropism is determined by many factors in both the virus and the host, including how the virus enters the host, how the virus spreads within the host (lymphatic, neural, or hematogenous spread), the permissiveness of specific cell types for the virus (as defined by receptors, cellular differentiation, and intrinsic cellular resistance to infection), the nature of innate and adaptive immune responses, and specific properties of tissues such as accessibility and effectiveness of the immune system (immunoprivilege). Each of these factors can play a determining role during viral infection and must be considered when defining mechanisms of viral pathogenesis.

Entry into the Host

A virus must access permissive cells to establish infection and therefore must overcome a series of anatomic and innate immune barriers to enter the host. The route of entry and the mechanisms of spread are therefore important determinants of viral tropism. The route and tissue through which a virus infects the host may be clear from epidemiologic studies. For example, both measles virus and VZV spread by the respiratory route, and polioviruses and noroviruses spread fecal–orally. However, even when the route of infection is known, the precise events involved in entry into the host are mostly unknown. Addressing this apparently simple question is a major challenge for pathogenesis research. The lack of knowledge of this critical step in pathogenesis is owing to the difficulties in studying viral spread under natural infection conditions when only a few infectious virus particles are sufficient to establish infection.

The critical determinants of viral spread include the form of the virus that spreads, the capacity of the virus to survive in the environment, the route of natural exposure to the virus, the mechanisms by which the virus gains entry, and the nature

of host barriers to infection. Host barriers may include non-specific barriers, barriers based on pattern recognition by the immune system, and barriers based on pre-existing adaptive immune responses.

Viruses may enter the body in different forms and via different vehicles.¹⁹⁸ The viral strategy for overcoming host barriers to entry is tightly linked to the form of the virus that spreads and how the virus is shed from the previously infected host. For example, viruses may enter carried in infected cells, may be injected via the mouth parts of arthropods,³⁰⁷ may be contained in droplets or fomites shed from an infected host, or may be ingested as free virus. To spread in a population, viruses may benefit from survival in the environment. For example, HIV is relatively unstable in the environment and does not effectively spread via environmental surfaces. This contrasts dramatically with noroviruses such as Norwalk virus that can spread via contact with contaminated environmental surfaces.¹²⁶

There are six primary portals of entry for viruses, each used by a variety of viruses. Five of these are epithelial surfaces: skin, conjunctiva, respiratory tract, gastrointestinal tract, and genitourinary tract. The sixth is the unique interface between the mother and the germ cell or the developing fetus.

Penetration Through Epithelial Barriers

The body is covered by epithelia, presenting a large surface for viruses to access. However, epithelia share several properties that inhibit viral entry. For example, epithelial cells are constantly turning over and being replenished; thus, cells that are contacted by a virus are shed continuously. The skin has an added protective mechanism, being many cells deep with the surface comprised of metabolically inactive cells that cannot support viral replication. In addition, barriers may be protected by low pH or secretions, including mucus.

Epithelial tissues are highly active immune organs. In all epithelia, DCs (e.g., Langerhans cells in the skin) serve as sentinels for invasion, having the capacity to, when activated, move to lymph nodes to induce immune responses. These sentinel cells play a dual role in infection, both as critical for induction of immunity and as cells targeted by viruses as an initial site of infection. For example, when VEE is inoculated into mice, the first cells infected are DCs; these cells rapidly move to draining lymph nodes, providing the virus access to the lymphatic system but potentially at the cost of the induction of immunity¹⁷¹ (Fig. 10.6). DCs lie beneath the intestinal columnar epithelium, and thus the intestine, as with skin, has a resident DC population plausibly involved in sentinel functions.^{146,202}

Intraepithelial lymphocytes are present in subepithelial and epithelial tissues, providing cells capable of protective immune responses in the most superficial layers of the body. In addition, epithelial cells themselves may be activated to express interferons or other antiviral molecules. In many sites, an invading virus is subject to inactivation by antibodies and complement. Even when a virus passes superficial epithelial barriers, the virus must confront the innate and adaptive immune response as well as an increasingly well understood set of intracellular barriers to infection collectively referred to as intrinsic cellular resistance to infection.

Viruses cross epithelial barriers through mechanical breaches (e.g., vectorborne delivery of arboviruses or bite wound delivery of rabies) or by accessing specialized cells

FIGURE 10.6. Infection of dendritic cells early after virus infection. To determine which cells are initially infected with VEE, a mutant virus expressing GFP was constructed and inoculated into the hindlimb (as described in reference 171). This mutant is capable of only a single round of infection; thus, GFP expression is restricted to cells infected by virus in the inoculum. Twelve hours later, the draining lymph node was resected and imaged for GFP expression. In the bottom image, dendritic cells within the lymph node express GFP, demonstrating that dendritic cells are initial targets of VEE infection. VEE, Venezuelan equine encephalitis virus; GFP, green fluorescent protein. (GFP image courtesy of Dr. Robert Johnston.)

within the epithelium. An excellent example of this latter situation is provided by reovirus, which accesses the Peyer's patch through specialized epithelial cells called M cells.^{54,147,200} Upon entry into the intestine, the reovirus virion is proteolyzed, triggering a remarkable structural transition with cleavage and loss

of $\sigma 3$, cleavage of $\mu 1$, and conformational changes in both $\sigma 1$ and $\lambda 2$ that generate the infectious subviral particle (ISVP) (Fig. 10.7). The ISVP binds to M cells, which then transport the virus into the Peyer's patch where productive infection occurs.

Vertical Spread of Viruses

Many viruses infect either the immature fetus or the newborn during the birth—a process referred to as vertical transmission. There are two mechanisms for entry into the developing fetus. The first is via placental penetration, as when a virus enters the fetus after invasion of the fetal circulation or amniotic fluid. Viruses such as HCMV and rubella can spread transplacentally,^{22,201} with devastating consequences for the developing fetus. Viruses such as human endogenous retroviruses (HERVs) can also be vertically transmitted via the germ line and constitute a significant fraction of the human genome.^{132,140} HERVs continue to proliferate within the genome and are likely to exert both beneficial and detrimental effects on their hosts. Refer to the eBook for more discussion of the vertical spread of viral elements encoded in the host genome.

Systemic Spread of Virus Infection

Once a virus has passed through epithelia or penetrated the placenta, the virus may still be far from its target cells and tissue(s). Viruses spread via three host systems that can provide access to a large number of tissues and cells: blood, lymphatics, and nerves. Although the blood is a major highway for spread of viruses through the host, many viruses use nerves or a combination of hematogenous and neural spread to access host tissues.

The level of viremia has been correlated with the severity of acute viral disease, the prognosis of chronic viral disease (as in HIV), the extent of viral dissemination, and the efficiency of viral spread between hosts.^{198,307} The level of viremia is a function of viral access to the blood, viral clearance from the blood, and the vehicle (plasma vs. cell associated) that the virus uses to travel through the blood. Viruses can access the blood either directly via introduction into the circulation, as by a needle or an insect bite, or indirectly after entering into and replicating in tissues. A very common finding is the rapid appearance of a virus in draining lymph nodes or in lymphoid structures such as Peyer's patches or tonsils. The connection between viral spread to lymphoid structures and subsequent spread to the rest of the host was recognized early on.^{73,182}

Entry into lymphoid tissue is a two-edged sword for the virus, as a facile route to access the viscera of the host but one that passes through the very tissues that generate adaptive antiviral immune responses. For viruses that primarily infect mucosal surfaces such as influenza virus, rotavirus, papillomaviruses, rhinoviruses, and noroviruses, it is likely that the primary effect of entry into the lymphoid system is the induction of antiviral immune responses. However, there are clear advantages for lymphoid invasion if the virus has tropism for cells of the immune system that are capable of circulating and entering tissues. For example, HIV and EBV each have tropism for lymphocytes for latent and/or productive infection, and both MCMV and HCMV can spread through the body in infected cells of the monocyte-macrophage lineage.

In many cases, viruses can access the nervous system by infecting neurons in the periphery and then spreading along

FIGURE 10.7. Reovirus entry into Peyer's patches in the intestine.

Reovirus enters the body as an intact virion. The action of proteases in the intestinal lumen cleaves proteins on the surface of the virion, generating a highly infectious form of the virus—the intermediate subviral particle—which interacts with the microfold or M cell overlying the Peyer's patch and is transported into the Peyer's patch where infection is established. From this point, the virus may enter the bloodstream or enter nerves for spread to organs such as the brain and spinal cord. (Reovirus images courtesy of Dr. Terrence Dermody.)

axons toward the CNS.¹⁹⁸ The classical example of this strategy is rabies virus, which spreads along nerves from the area of inoculation to the CNS.¹³¹ The time between inoculation and development of signs and symptoms of rabies encephalitis depends on the length of the nerves between the site of inoculation and the CNS. The virus travels up nerves toward the CNS at a rate of 50 to 100 mm/day, and the disease can be cured by surgical removal of the infected limb as long as the virus has not entered the CNS.^{13,131} For example, if the initial bite is on a lower extremity, there is a longer time within which vaccination and passive transfer of rabies-immune antibody can be effective than if the bite is on the face.¹³¹ Studies with several viruses, including HSV, pseudorabies virus, and reoviruses, have been used to elucidate the viral and cellular determinants that regulate viral spread through neural tissues, including sophisticated genetic and molecular mechanisms that regulate viral anterograde and retrograde axonal transport. Importantly, the immune system can also modulate neural spread. For example, antibodies can interrupt many of the steps in neural spread of reoviruses to and within the CNS (Fig. 10.8). Refer to the eBook for an expanded discussion of the mechanisms of neural spread of viruses.

Determinants of Cell, Tissue, and Species Tropism

Once a virus has spread via lymphatic, hematogenous, or neural routes, a fundamental determinant of viral pathogenesis becomes the distribution of the virus between and within tissues of the host. Distribution of virus in tissues is a dynamic process determined by competing processes, including the speed of viral replication, the presence of specific viral receptors

or other pro-viral factors that permit viral entry or replication, viral mutation rate, viral virulence genes, host susceptibility and resistance genes, and innate and adaptive immunity. It is useful to think of tissue distribution of a virus as an ongoing battle between the virus and the host being played out in different tissues. This battle has very local aspects, such as the contact between a virus and a specific cell or the contact between an NK cell or cytolytic T cell and a virus-infected cell. However, the outcome of this battle is also determined by effects over short distances in tissues, as, for example, the effects of host cytokines or virus-encoded soluble proteins that evade or subvert host responses. Lastly, there are long-range effects of host responses on infection, including production of antibody, synthesis of stress steroids, activation of the bone marrow to produce inflammatory cells, stimulation of the liver to synthesize and release acute-phase reactants such as complement proteins, and stimulation of autonomic centers in the brain to produce fever.

The Role of Viral Receptors in Cell, Tissue, and Species Tropism

An important step in viral infection, and a primary determinant of the distribution of virus between and within tissues, is the interaction of a virus with specific receptors on permissive cells. Receptor expression plays a major role in determining the tropism of several viruses, including poliovirus and measles virus, and the use of molecular tools, including transgenic mice, expressing the virus-specific receptors provides key insights into the role of receptors in regulating viral tissue tropism and pathogenesis. The importance of viral–receptor interactions is further illustrated by the fact that zoonotic viruses must often

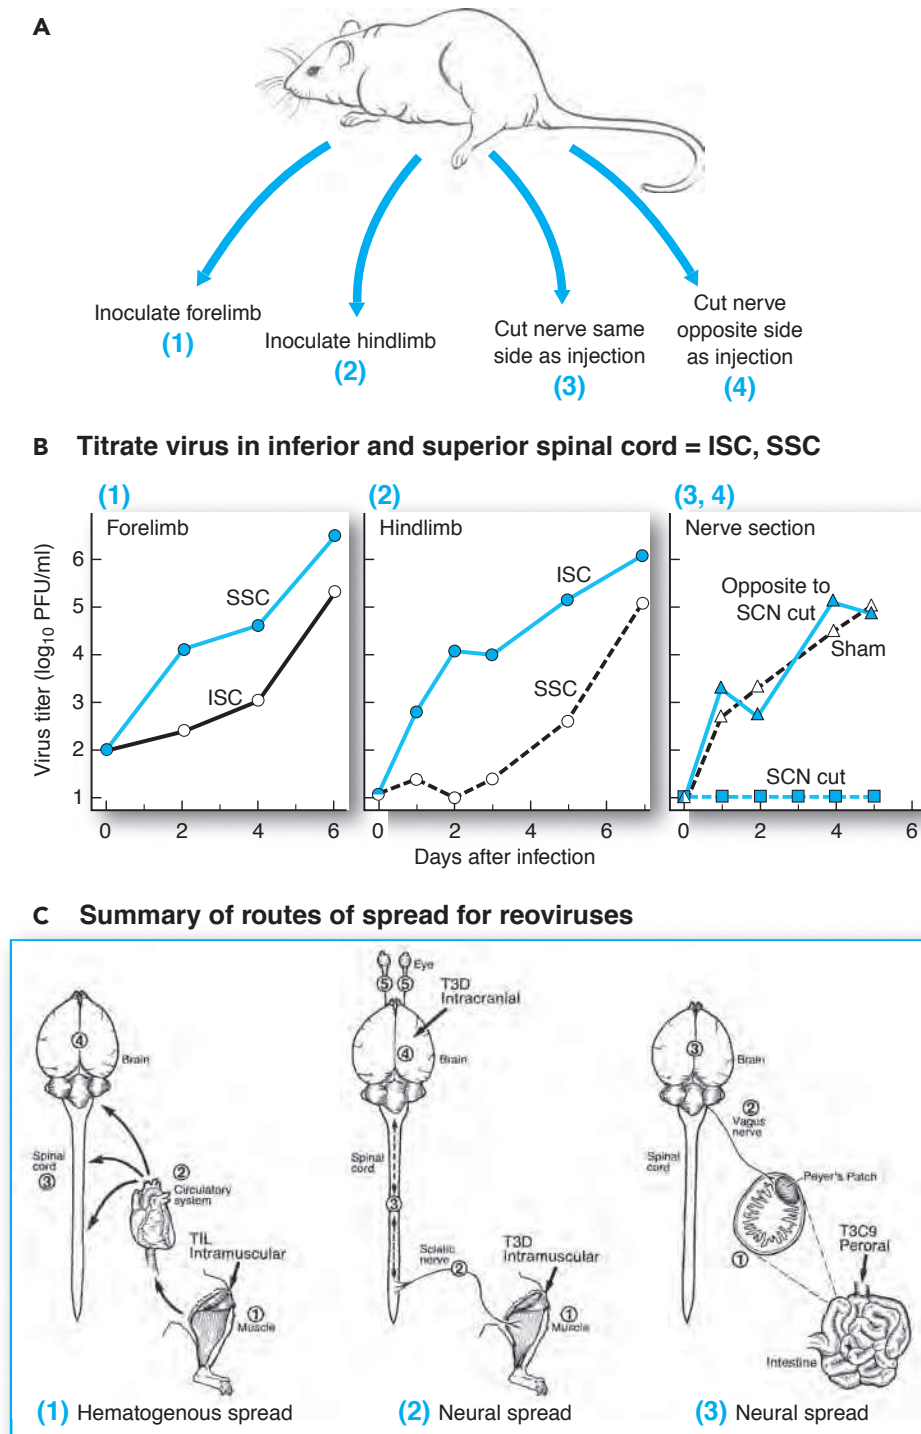

FIGURE 10.8. Neural versus hematogenous spread of reoviruses. **A:** Experimental design. **B:** Viral titrations after various experimental manipulations. **C:** Summary of the routes of spread of reovirus serotype 1 strain Lang (T1L), serotype T3 strain Dearing (T3D), and serotype 3 clone 9 (T3C9). Evolution of viral disease. In: Nathanson N, Ahmed R, Gonzalez-Scarano F, et al, eds. *Viral Pathogenesis*. Philadelphia: Lippincott-Raven; 1997:353–369.)

adapt to receptors in their new host species to effectively cause disease and disseminate, as was the case with SARS.¹⁶¹ These binding interactions are necessary for infection but are often not sufficient to explain all aspects of cell, species, and tissue tropism. For example, CD4 and chemokine receptors such as CCR5 or CXCR4 confer susceptibility to HIV infection; however, permissiveness is also controlled by cytoplasmic proteins that restrict HIV infection.

Often, viruses use a binding receptor to increase the concentration of virus at the cell surface and one or more entry receptors. An example of this latter strategy is HSV, which interacts with specific sulfated sugars on heparan sulfate²⁵⁵ in a process that enhances infection but is not required if a cell expresses an entry receptor such as the appropriate nectin.^{88,263,269} Another example of this strategy is utilized by serotype 3 reoviruses, which interact with sialic acid via one portion of their cell attachment protein $\sigma 1$ and the protein JAM1 via another portion of the $\sigma 1$ protein.⁵⁴ Importantly, the interaction with the broadly expressed carbohydrate sialic acid has been shown to be important in the tropism of the reovirus *in vivo*, indicating that even interactions with ubiquitously expressed molecules can play a role in cell and tissue tropism.⁵⁴ Tropism can also be conferred by interactions between viral cell attachment proteins and proteases, as is seen with Newcastle disease and influenza viruses.^{41,191} Refer to the eBook for a more extensive discussion of how receptor tropism affects viral pathogenesis using poliovirus infection as an example.

Innate Immunity and Intrinsic Cellular Resistance to Infection Determine Tropism

Factors in addition to specific receptors play a major role in determining viral tropism. Tropism can be determined by proteins responsible for cell-intrinsic defense against viral infection, transcription factors, cell cycle regulators, and microRNAs. For example, the liver-specific host microRNA miR-122 is essential for robust HCV replication,¹³⁷ and inhibition of miR-122 in nonhuman primates limits HCV replication.¹⁵¹

Once a virus has bound to a cell and delivered its genome or capsid to the cytoplasm, a series of events occur that can have a profound effect on the viral cell tropism. These events likely explain why receptor expression does not always explain the cell and tissue tropism of a virus. The host cell expresses on its cell surface and in its cytoplasm molecules that can either directly inhibit viral replication (intrinsic cellular resistance to infection) or can induce a signaling cascade that in turn generates antiviral molecules (innate immune responses). Together, these molecules and pathways are determinants of both the permissiveness of cells for viral replication and species tropism. It is likely that mechanistic relationships will be discovered between molecules involved in innate immunity and intrinsic cellular resistance to infection as more is learned about each of these two important processes.

Molecules involved in innate immunity can be important components of tissue and species tropism. This is illustrated by myxoma virus, which does not normally infect mice but readily infects murine cell lacking type I interferon responses and causes lethal disease in STAT-1 deficient mice.³⁰⁵ Intrinsic cellular resistance to infection is also conferred by molecules such as the TRIM or APOBEC proteins that restrict retrovirus infection. Importantly, allelic variations in the genes involved in these processes may contribute to regulation of viral pathogenesis.

Immunoprivilege

One important determinant of viral tropism is the fact that the innate and adaptive immune systems are not equally efficacious at clearing virus infection from all tissues. The concept that the immune system is selectively ineffective at clearing virus infection from specific tissues is referred to as immunoprivilege. Immunoprivilege plays a significant part in the pathogenesis of many viruses but has been best studied in experimental murine pathogenesis models. For example, in studies of LCMV infection of mice,^{32,38} many organs including liver, spleen, lung, and pancreas are cleared relatively efficiently within 30 days of transfer of immune cells. However, virus persists in the CNS for up to 90 days and in the kidney and genitourinary system for more than 200 days, indicating that both the CNS and the genitourinary tract are immunoprivileged. These data also show that immunoprivilege is a relative term, with the efficacy of the immune system varying depending on when infection is analyzed. Analysis of the mice at a time point more than 90 days after transfer of immune cells identifies only the genitourinary tract as immunoprivileged (Fig. 10.9).

It is likely that the selective inability of the immune system to clear virus infection from certain tissues is owing to a combination of two interrelated factors. The first is intrinsic limitations of immune system function in certain tissues or to limited capacity to address infection of certain cell types. For example, CD8 T cells may be more effective at eliminating infection from major histocompatibility complex (MHC) class I-expressing hepatocytes than from neurons that do not express MHC class I molecules. The second factor is viral evasion of immunity. An example of this is the capacity of HSV to evade clearance by the host immune system via establishment of latency in neurons. It is plausible that in most cases immunoprivilege is owing to a combination of both viral strategies and cell- or tissue-specific limitations in the efficacy of the immune response. The mechanisms responsible for immunoprivilege are poorly defined at the cellular and molecular level.

Cellular Differentiation as a Determinant of Viral Tropism and Pathogenesis

Another important determinant of viral tissue distribution is cellular differentiation. Thus, cells at different stages of differentiation may have specific properties that favor or disfavor viral infection or replication. This is especially true in a tissue responding to virus-induced damage. For example, when hepatocytes are damaged during chronic HBV or HCV infection, the liver regenerates, providing viruses with access to cells in different differentiation states.

Many viruses take advantage of differentiated functions of the cells that they target. For example, HSV establishes latency in fully differentiated neurons, and EBV latently infects memory B cells; in each case, the reservoir for chronic infection is a particularly long-lived cell type. The lytic cycle of gene expression for both HIV and EBV is triggered by induction of lymphocyte activation and differentiation. In each case, a specific relationship between a virus and a certain differentiation state of an infected cell contributes to viral pathogenesis.

Papillomavirus infection of the skin provides an outstanding example of the impact of cellular differentiation on pathogenesis^{26,190} (Fig. 10.10). In normal skin, basal stem cells give rise to ever more differentiated cells that move toward the skin surface, lose their nucleus, become cornified, and are finally

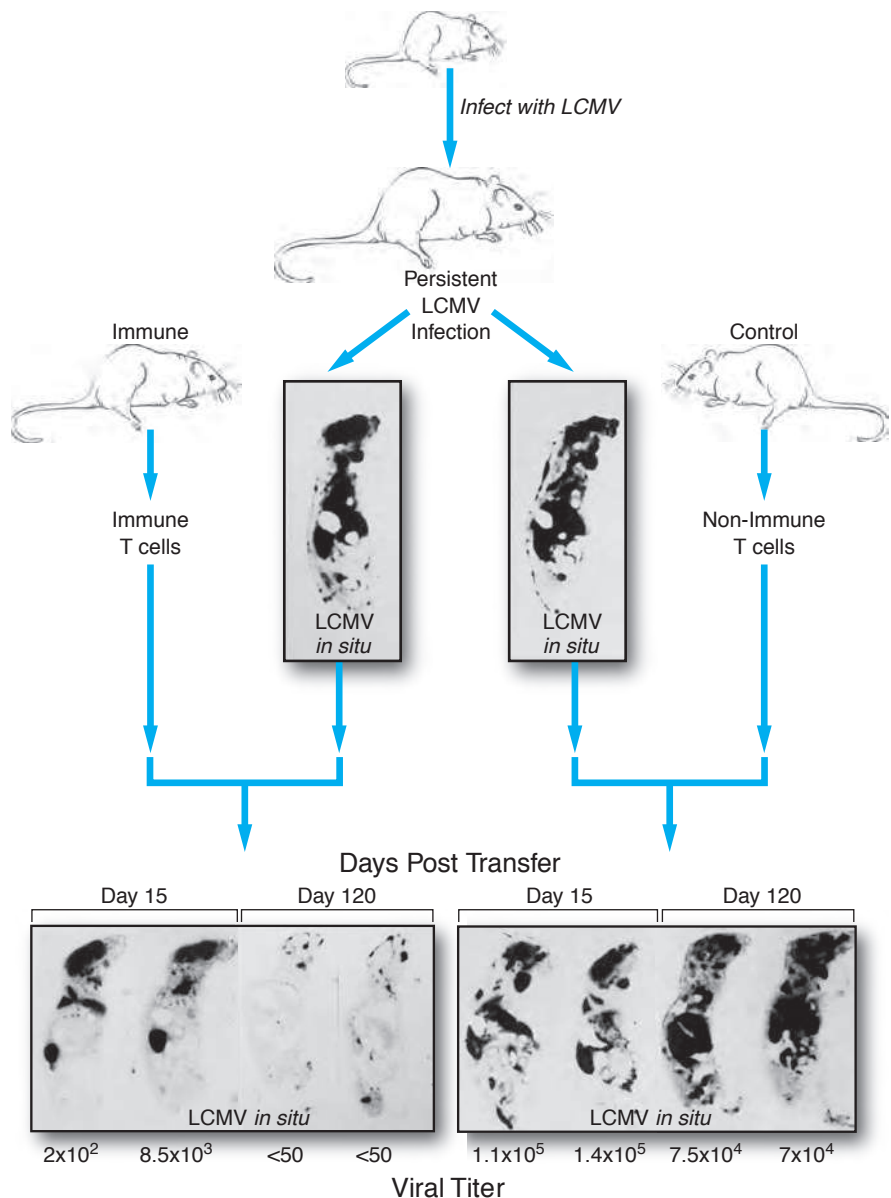

FIGURE 10.9. LCMV clearance by immune T cells reveals immunoprivileged tissues.

Shown is the pattern of clearance of LCMV after transfer of either immune or control T cells into mice with persistent LCMV infection as described in reference 208. The clearance of virus is indicated both by the viral titers shown and by the *in situ* hybridization signal from cross sections of the whole mouse. LCMV, lymphocytic choriomeningitis virus. Cytoimmunotherapy for persistent virus infection reveals a unique clearance pattern from the central nervous system. *Nature* 1986;321:239–243; courtesy of Dr. Michael Oldstone.)

shed. Papillomaviruses infect basal stem cells of the skin, where they can persist in a latent state for prolonged periods. Activation of a program of gene expression initially involving the expression of E6 and E7 proteins results in cell cycle progression, inhibition of apoptosis, and viral replication. As infected cells differentiate and move toward the skin surface, they become permissive for expression of genes involved in viral replication and assembly (see Fig. 10.10). The normal differentiation process is subverted by the virus, resulting in retention of the nucleus and synthesis of proteins required for viral DNA and protein synthesis. The virus assembles and is released from the skin in shed cells.

The principle that cellular differentiation is a determinant of viral pathogenesis is very important and general. When tissues are damaged, stem cells are activated to generate new cells with consequent proliferation of somatic cells and differentiation into cells such as hepatocytes, endothelial cells,

or epithelial cells. These processes are plausibly subverted by several viruses, many of which grow optimally in replicating cells. One consequence of this principle is that the full potential of a virus's genetic program may not be revealed in a cell line that is transformed or represents a single differentiation state within a particular cell lineage. It is plausible that, as with papillomaviruses, many viruses have genes that play specific roles in the cell at certain stages of differentiation and thereby contribute to pathogenesis.

FATE OF THE INFECTED CELL, TISSUE, AND HOST

The presence of a virus in a tissue may or may not result in damage. The variables that determine the fate of the infected tissue

Virus Infection Changes with Differentiation of a Cell

and host are complex and involve the interplay between the virus and its cytopathic potential; the age, sex, and nutritional status of the host; the regenerative capacities of different primary cell types; whether the immune system damages the tissue as part of the protective response; whether the virus induces autoimmune responses; and perhaps most importantly, whether the virus is ever cleared from the tissue and, if not, the nature of residual virus infection. Determinants of tissue damage may be local in nature, such as the death of infected cells owing to viral cytopathicity or killing by immune cells, or operative over longer distances, as in the case of vascular damage leading to ischemia, systemic hormonal and cytokine responses, induction of fever or cachexia, cytokine induction of the death of uninfected cells, metastatic tumors, or virus-induced autoimmunity.

Although viruses can directly kill infected cells as they replicate, one is always confronted with the question of whether tissue damage is directly caused by the virus or is indirectly caused by the immune system; what is the balance between the protective and destructive capacities of the immune system? Additionally, viruses can damage the host indirectly by making the host susceptible to secondary infections or by altering fluid and electrolyte balance, as in the case of dehydration induced by gastroenteritis. It has recently been found that virus infection can trigger, in a host with a specific genetic makeup, novel disease phenotypes in uninfected cells,⁴⁰ and therefore that a virus can have a substantial effect on diseases that are highly specific to a given constellation of genes in the host. Thus, in many situations, the pathogenesis of disease may be independent of whether virus replication *per se* induces the death of infected cells.

Age as a Determinant of Susceptibility to Viral Infection

Many viral infections are far more severe in young than older hosts^{159,256}—an increase in severity that often correlates with increased replication and dissemination of virus. For example, suckling mice have long been used to isolate new viruses because they have greater susceptibility to virus infection than mature mice. The susceptibility of young mice to Sindbis virus infection is a striking example.¹⁵⁰ Intracerebral inoculation

of 1-day-old mice with most strains of Sindbis virus results in rapid death, extensive neuronal apoptosis, and high levels of viral replication. In contrast, the same viral inoculum in 4-week-old mice results in a nearly 10-fold lower viral replication, no death, and no neuronal apoptosis. This observation extends to many other viruses, including poliovirus, where 2-week-old poliovirus receptor transgenic mice are 10,000-fold more susceptible to paralytic disease than adult mice.⁵³ All measles virus receptor transgenic mice inoculated at 1 to 6 days of age succumb to lethal infection, whereas mice aged 30 to 60 days at inoculation survive.^{153,236}

The practical importance of this principle is reflected in studies in primates with potential live attenuated SIV vaccines and in the epidemiology of human HBV infection. Vaccination of an adult monkey with live attenuated SIV viruses lacking nef or combinations of nef and other genes significantly protects against SIV challenge.³¹¹ However, inoculation of neonatal animals with the same live attenuated vaccine virus results in progressive immunodeficiency. Similarly, whereas adults infected with HBV often clear the infection, exposure of human neonates to HBV results in a very high level of chronic infection.³¹⁵ Age dependence of virus resistance does not always favor older hosts. For example, West Nile virus encephalitis is more common and more severe in older hosts,¹¹⁴ and lethality after SARS infection is significantly higher in people older than 60 years of age than in younger people.^{62,219} This is also the case in mouse models of SARS infection.^{244,246}

Together, these data indicate that age plays a critical role in determining viral virulence. The mechanism(s) responsible for this are incompletely understood. It is commonly considered that maturation of the immune system explains increased resistance to infections seen in older hosts. However, this has not been rigorously demonstrated as the reason for age-dependent susceptibility to viral infection. Other age-dependent processes, such as cellular differentiation and proliferation, may play a role as large as that of the immune system in age-related susceptibility. For example, the genes expressed in the nervous system during infection of younger versus older hosts differ,^{150,213} indicating that there are fundamental differences in how older and younger tissues respond to viral infection.

Fate of Infected and Uninfected Cells in Tissues

A primary determinant of the tissue damage and pathology observed after viral infection is the fate of the infected cell. It is often unclear why cells in tissues die when infected by viruses, and the extent to which cell death is destructive or protective in tissues is often uncertain. On the one hand, death of infected cells is harmful if those cells are essential to the host; on the other hand, death of an infected cell may inhibit viral replication with the sacrifice of one cell contributing to the protection of other cells. The immune system has many mechanisms for killing infected cells, arguing that the death of infected cells can benefit the host (Chapters 8 and 9). The death of cells in an infected tissue may be indirect, with uninfected cells dying owing to cytokines, bystander killing by leukocytes, or ischemia. The consequences of viral infection range from rapid destruction of tissue cells, as seen with variola or Ebola viruses, to continuous replication in the absence of severe cytopathology, as seen with LCMV, to the establishment of latency, as seen with herpesviruses.

Direct Killing of Cells by Viruses

Cytopathic effect is defined as the destructive consequences of virus infection on cells. Direct killing of cells by viruses may be attributable to viral subversion of cell metabolism for replication or to cell-intrinsic programmed cell death pathways such as necrosis, apoptosis, or nonnecrotic and nonapoptotic cell death. Despite the great importance of understanding the specific mechanisms responsible for virus-induced tissue damage, the balance between virus-induced cell death and cell death owing to host programs induced by the presence of the virus is very poorly understood in most cases.

The term *cytopathic effect* is most commonly used to describe the consequences of infection in cultured cells. Cell death that occurs in a cultured cell may or may not reflect the process of cell death that occurs *in vivo*. An advantage of studying cell death and cytopathicity in cultured cells is that the interaction between the virus and the cell occurs without cell-extrinsic factors, with exception of those owing to autocrine stimulation (e.g., the expression of interferons by infected cells). A disadvantage of this approach to studying cell death is that events in cultured cells may have little relationship to what happens in primary cells in an infected tissue.

It is easiest to ascribe cell killing to direct viral effects, rather than immunopathology or ischemia, when death of virus-infected cells occurs in the absence of inflammation or extensive tissue damage. For example, in both Sindbis and rabies, virus kill neurons in the absence of extensive inflammation. Further proof that viruses can directly damage tissue without invoking indirect effects of immunopathology comes from the susceptibility of SCID mice and *RAG* gene-deficient mice, which cannot mount adaptive T- or B-cell responses, to several different viruses. In these cases, death of host cells cannot be attributed to the immunopathologic consequences of adaptive immunity, although contributions from innate immunity cannot be ruled out. It is important to remember that the presence of inflammation does not necessarily indicate the participation of inflammatory cells in the killing of infected cells. Inflammatory cells may be beneficial or present as a host response to killed cells and tissue damage rather than being participants in the death of infected cells.

Killing of Cells by Cell-Extrinsic Effects of the Immune System

Not all cell death in an infected tissue is a result of direct viral effects or cell-intrinsic mechanisms of programmed cell death triggered by the presence of the virus. The host has many cell-extrinsic mechanisms for initiating apoptosis or lysis of infected cells via cytokines, serum proteins such as complement, and proteins such as the granzymes that are injected via perforin into infected cells by leukocytes (Chapters 8 and 9).

The role of cell killing by the lytic activity of granzymes is important because perforin- and/or granzyme-deficient mice are susceptible to coronaviruses, West Nile virus, LCMV, ectromelia virus, HSV, Theiler's virus, MCMV, and murine γ HV68,^{165,166,188,220,254} and a human with a mutation in perforin has been described with chronic active EBV infection.¹³⁹ As detailed later, these cell killing pathways can contribute to virus-induced immune pathology, as studies in HBV transgenic mice in which cytolytic antiviral CD8 T cells mediate liver disease show that both perforin- and FAS-dependent pathways contribute to liver destruction.¹⁹³

The complement cascade is a two-edged sword important for antiviral immunity but can also contribute to virus-induced tissue damage.^{25,268} Complement proteins are involved in induction of antibody and T-cell responses, trapping of viral antigen on antigen-presenting cells, induction of chemotactic and vascular permeability changes in infected tissues, and activation of leukocytes. In addition to being immunoregulatory, complement can lyse both virus-infected cells and lyse or neutralize virions.^{25,79,178,294}

Clearance of Virus Infection and Chronic Viral Infection

A fundamentally important variable in viral pathogenesis is whether the immune system can clear a virus from the body. Some viruses are readily cleared but can do significant damage to the host during their brief time of residence in the body. An example is variola virus, which causes smallpox. This pattern of acute infection (see Figs. 10.1 and 10.3) is associated with development of sterilizing immunity and effective resistance to reinfection. Many viruses for which effective vaccines are available fall into this category. Other viruses are less amenable to elimination by the immune system, resulting in latent, chronic, or progressive infection (see Fig. 10.1). Examples of chronic viral infections of great medical significance are those caused by HIV, HCV, and HBV. Other chronic infections are less consistently harmful to their hosts but do cause significant disease. Examples include herpesviruses such as EBV, VZV, HCMV, and HSV, each of which permanently infects most human beings. It is possible that such chronic infection can, in addition to causing disease in rare cases, provide a symbiotic benefit to the host via chronic stimulation of the innate immune system, including macrophages and NK cells.^{17,302,310,326,327}

Between the extremes of complete clearance and establishment of chronic infection, there are viruses that persist in a small proportion of hosts. For example, measles virus persists in the CNS of a small proportion of infected persons, causing subacute sclerosing panencephalitis (SSPE). In SSPE, a chronic CNS infection with measles leads to a progressive destruction of neurons and often to death. Importantly, SSPE is associated

with an unusual pattern of mutations in defective measles viruses that persists in the CNS, with mutations in several proteins and a bias toward U to C mutations in the matrix protein.^{45,209,243} In the murine measles virus receptor transgenic system, transient infection with LCMV predisposes to development of an SSPE-like disease.²⁰⁹ This is a paradigmatic example of how a common infection (measles) may cause pathology triggered by a second infection.

Whereas persistence of certain viruses is related to disease in a proportion of infected hosts, the role of persistent infection is more controversial for many other viruses (see Fig. 10.1). For example, coxsackievirus RNA persists in the hearts of some persons with chronic myocarditis, and poliovirus RNA may persist in the CNS of a proportion of persons who develop “postpolio” syndrome.^{142,312} These situations are not as well understood as SSPE or chronic infections with herpesviruses, retroviruses, HCV, or HBV. However, the data suggests the hypothesis that persistence of either virus or viral genomes may contribute to disease in some cases, and it seems highly likely that additional examples of similar phenomena will be detected as unbiased and highly sensitive next-generation sequencing technologies are applied in clinical settings to detect viral genomes.

Tissue Damage During Beneficial Immune Responses Is a Necessary Evil

Certain viruses, such as HCV, HBV, HIV, SIV, and LCMV, can persistently replicate in tissues despite an active adaptive immune response. Although the immune response is ineffective at clearing the virus, activated immune cells and cytokines are still capable of killing host cells. Even when the immune system can clear a virus, these adaptive immune mechanisms may cause significant damage to host tissues. Importantly, the innate immune system can also contribute to host disease in the setting of acute infection, as has been shown, for example, for influenza.²⁸¹

Although there are clear examples in which the immune system is primarily responsible for virus-induced tissue pathology, and thus disease is immunopathologic, the situation is seldom that simple. The antiviral immune response has two faces: a beneficial face as the host system responsible for curing infection and a harmful face via induction of tissue pathology and systemic toxicity. This sets the stage for consideration of one of the most complex topics in viral pathogenesis: the relationship between immune-mediated damage and clearance of infection.

It is not always true that the function of the immune system causes pathology. For example, protective effects of antibody that do not damage tissues are seen in most if not all viral infections. Sindbis virus is cleared from neurons by antibody to the E2 envelope glycoprotein in the absence of neuronal loss,¹⁶⁰ and antibody to measles virus can alter expression of measles proteins in infected cells.^{80,82} Antibody can inhibit the neural spread of viruses, such as reovirus, and can act inside cells to inhibit reovirus and West Nile virus replication.^{283,298,299} Whereas immunity can be beneficial without harming host cells, in other cases, the more harmful face of the immune system is prominent and tissue injury is associated with immune-mediated clearance of infection.

A clear example of the two-faced nature of immunity comes from studies of HBV. HBV DNA replication occurs for weeks before induction of a significant immune and inflammatory response or significant release of serum alanine

aminotransferase (sALT), a marker of hepatocyte lysis, into the circulation^{314,315} (Fig. 10.11). Damage to the liver does occur during the latter stages of clearance of HBV DNA from the liver, as evidenced by increases in both sALT and the number of apoptotic hepatocytes, and the induction of this damage correlates with the appearance of CD8 T cells and IFN γ mRNA in the liver^{314,316} (see Fig. 10.11). Thus, active immune responses and clearance of the last vestiges of infection are associated with significant tissue injury.

The mechanisms underlying these processes have been further elucidated using transgenic mice that express viral antigen and nucleic acids in all hepatocytes and produce infectious HBV in serum. Using these mice, it has been shown that virus replication can be limited and viral protein and nucleic acid can be cleared from hepatocytes without killing the hepatocytes^{100–103,286} via a mechanism that depends on interferons and tumor necrosis factor (TNF). However, these same studies also demonstrated that virus-specific T cells can contribute to the induction of liver injury. These results were further validated by studies in chimpanzees, where depletion of CD8 T cells resulted in delayed viral clearance, and the kinetics of viral clearance and alanine aminotransferase (ALT) induction suggested that virus was cleared in large part by noncytolytic mechanisms but that the CD8 T cells also drove final resolution of infection and subsequent liver damage through cytolytic mechanisms. These studies illustrate the potential dual nature of the immune response in mediating viral clearance while also causing tissue pathology during the clearance process.

Immunopathology Occurs When the Immune System Goes Too Far

In some cases, the balance between the protective effects of immunity and the harmful effects of immunity clearly shifts to immunity being the primary cause of tissue pathology and even death of the host.^{32,323} These processes can be driven by overactive innate immune responses, which result in inflammatory responses that drive virus-induced tissue pathology and disease,³²⁸ nonspecific cell killing, or even induction of autoimmunity by the host adaptive immune response. The balance between acceptable tissue damage associated with viral clearance and immunopathology is determined by the effectiveness of the immune system in clearing the infection. For example, even severe hepatitis would be an acceptable outcome of HCV infection if the virus could be cleared; however, the immune response to HCV infection is often ineffective. Immunopathology can be attributable to either T- or B-cell responses or to innate immunity and may be the consequence of virus-induced immune responses to either viral antigens or, in the case of induced autoimmunity, host antigens.

An excellent example of immunopathology owing to B-cell responses is the kidney damage done by immune complexes generated during the continuous replication of viruses such as LCMV, lactic dehydrogenase virus, Aleutian disease of mink, HBV, HCV, or murine retroviruses.^{110,118,210,211,232,295} In these cases, circulating immune complexes containing viral antigen are deposited in the kidney with consequent activation of complement and cellular inflammation that results in damage to the renal filtration apparatus of the glomerulus.

The existence of T-cell-mediated immune pathology was first demonstrated using the LCMV system.^{32,38} Infection of adult mice by the intracerebral route with LCMV

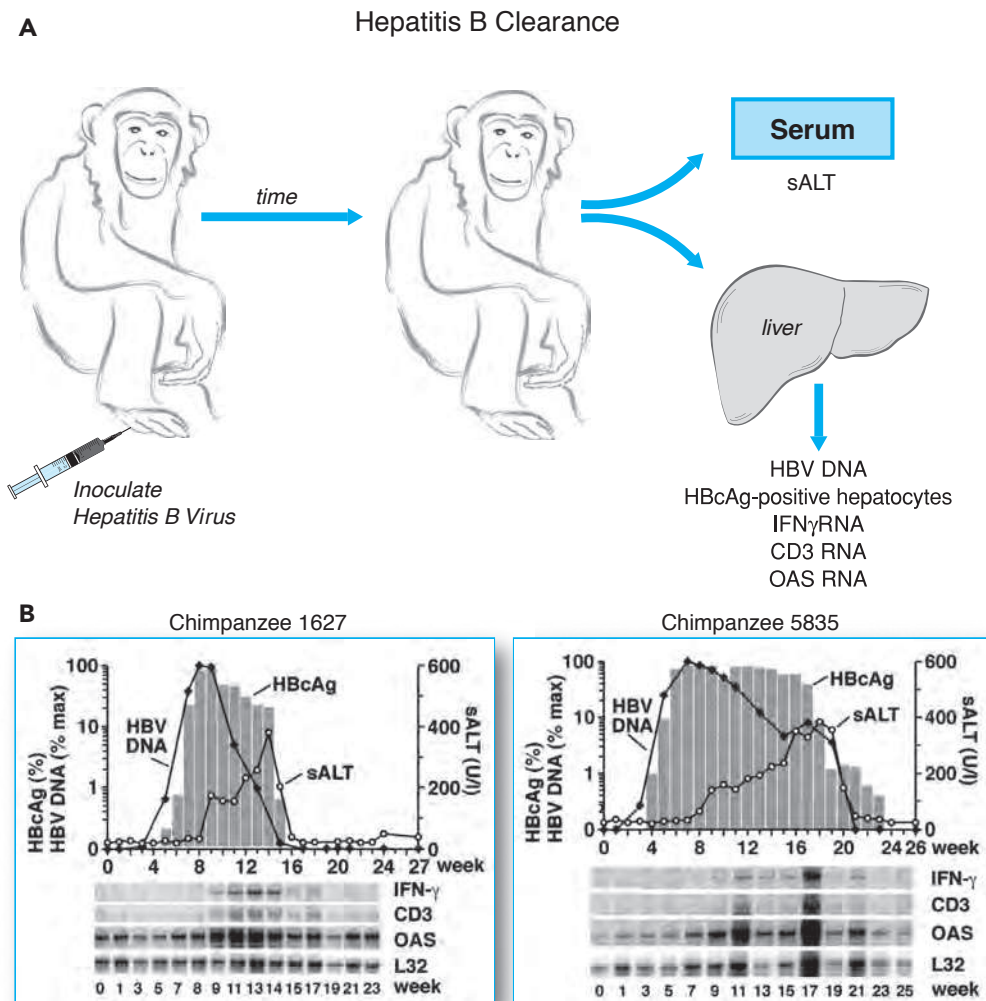

FIGURE 10.11. Clearance of HBV is associated with liver damage. Chimpanzees were infected as shown in **panel A** as described in detail in reference 314; at various times after infection, serum samples or liver biopsies were taken and analyzed for sALT and various parameters of HBV infection. Intrahepatic HBV DNA (*black squares*) is expressed as a percentage (% max) of the peak HBV DNA levels in the liver of each animal. Hepatitis B core antigen–positive hepatocytes (*gray bars*) are expressed as percentage of the total number of hepatocytes. sALT (*open circles*) is expressed in units per liter. Intrahepatic expression profiles for IFN γ , CD3, and 2'5'OAS were determined by RNase protection assay. HBV, hepatitis B virus; sALT, serum alanine aminotransferase; IFN γ , interferon- γ . (Adapted from Wieland S, Thimme R, Purcell RH, et al. Genomic analysis of the host response to hepatitis B virus infection. *Proc Natl Acad Sci U S A* 2004;101:6669–6674.)

results in death attributable to inflammation of the meninges and choroid plexus termed *choriomeningitis*.^{32,38,177} The importance of this model is that, as opposed to most viral infections in which depletion of T cells worsens infection, for LCMV depletion of T cells protects against disease.^{32,38,157,186} Further studies have demonstrated that LCMV-specific CD8 T cells were responsible for virus-induced immune pathology.³²⁵

These experiments in the LCMV system show that CD8 T cells, in addition to their protective capacities, can be responsible for destruction of many different types of virus-infected cells. Why is the balance of protection versus immunopathology tipped toward immunopathology for LCMV? The most obvious reason is that the virus is largely noncytopathic, thus the

presence of the virus in the host even over long periods does limited direct cellular damage. In this view, CD8 T cells kill virus-infected cells that would not otherwise die, resulting in immunopathology. This makes a plausible case for a key role for immunopathology in chronic diseases attributed to largely noncytopathic viruses such as HBV and HCV.

Virus-Induced Autoimmunity

A variant mechanism of immunopathology is the induction of autoimmunity by virus infection.^{21,181,207,304} The contributions of autoimmunity to tissue pathology associated with viral infection, or putatively associated with viral vaccination, remain quite controversial. The role of autoimmunity in virus infection and postinfection syndromes has been studied in

several systems, and viruses have at one time or another been candidate etiologic agents for many autoimmune or inflammatory diseases in humans, including rheumatoid arthritis, multiple sclerosis, Crohn's disease, myocarditis, uveitis, hepatitis, Sjögren's syndrome, and type 1 diabetes.

To date, unequivocal proof of the role of a specific virus in a human autoimmune disease has been lacking, although this is an important area of interest. The presence of immune responses to self-antigens after virus infection is common; however, these responses should not be confused with a pathological role for self-responses in virus-induced pathology. Moreover, when studies in some viral models that have been touted to represent autoimmunity are examined very carefully, the persistence of viral genome, and perhaps protein, provides a plausible alternative to autoimmunity as a mechanism. This is true for coxsackievirus-induced myocarditis,³¹³ underlining the importance of careful virologic assessment of potentially autoimmune phenomena.

A proposed mechanism for the induction of autoimmunity is molecular mimicry between virus and host antigens leading to a breakdown of self-tolerance.²⁰⁷ This might plausibly occur in the setting of virus-induced tissue damage and inflammation. Since the first proof that this can happen, numerous experiments supporting the concept that molecular mimicry can trigger autoimmunity have been published. The opportunity for molecular mimicry for T cells is provided by the degenerate recognition of peptides by even clonally expanded antigen-specific T cells, making it more likely that antiviral T cells could recognize peptides derived from the host proteome.

The potential for molecular mimicry to cause virus-associated pathology has been proven using transgenic mice engineered to express the LCMV nucleoprotein or glycoprotein under the control of the insulin promoter in the insulin-producing islet cells of the pancreas.^{81,204,206,212,303,304} Infection of these mice with LCMV can trigger diabetes. In this case, LCMV infection triggers a T-cell response to the viral protein expressed in the pancreas as a pseudo-self-antigen. Autoimmune T-cell responses can also develop during persistent virus infection when viral and self-proteins do not demonstrably cross-react—a process termed *epitope spreading*.^{181,222} In this process, it may be that the inflammatory response to chronic infection results in the induction of T-cell responses to self-proteins via breakdown in self-tolerance and expansion of rare clones of autoreactive T cells that escape negative selection in the thymus. Although these studies demonstrate that a virus can induce disease by inducing responses to proteins expressed in a host tissue, studies proving that this mechanism is responsible for a specific human disease have not been published.

VIRAL DETERMINANTS OF VIRULENCE

Niche-Specific Virulence Genes

Viral genes and virulence determinants are important indicators of viral pathogenesis and viral virulence. Examples of specific properties of viruses that contribute to virulence abound in the literature, and many—including tropism, the capacity to persist, and the capacity to kill cells—have already been discussed. *Virulence* is a general term representing the severity of viral

infection for the host. However, specific viral genes and properties most often play a role in a very specific tissue, at a certain time, at a very specific bottleneck in infection, or to counter a very specific host response to infection. A useful concept is that such genes are niche specific, having functions in a single aspect of infection defined by time, tissue, and stage of infection or host response. Thus, virulence is the sum of the actions of multiple niche-specific viral genes and virulence determinants that play their specific roles in limited settings *in vivo*.

The concept that viral virulence genes and virulence determinants have niche-specific roles *in vivo* during infection is important for understanding experimental pathogenesis research. *In vivo* readouts of infection often depend on a single route and dose of infection, are often measured in a genetically homogeneous host, and commonly rely on a limited set of assays for viral infection such as death of the infected host, growth of virus in a certain tissue at a certain time, or severity of tissue pathology. The experimentalist is rarely able to mimic the entire process of pathogenesis under physiologic conditions, and so the virus is not asked to perform all of the tasks for which it has evolved in nature. Experiments performed under such conditions may reveal a minor, or even no, contribution of a niche-specific viral virulence gene or allele to infection as measured by a limited set of assays in a given experiment. This type of negative data is fundamentally unrevealing. The gene or allele under study may have a significant role that would be revealed by further experimentation that quantitatively evaluated the niche within which the gene functions. It is plausible that every viral gene has been under considerable evolutionary pressure and that the mere presence of the gene indicates that the gene has an important function for the virus. Exceptions may be found when a virus has recently jumped from one species to another; however, even in that setting, the pressure to utilize the limited viral genome parsimoniously likely results in rapid selection against useless genes.

It is therefore true that niche-specific functions of viral genes may only be identified in specific experimental conditions. Examples of this phenomenon abound and include the role of the *M3* gene of murine γ HV68 that encodes a chemokine scavenger. *M3* mutant viruses are completely normal in a broad range of properties *in vivo* in mice, including replication in many tissues and the establishment of viral latency. However, the gene contributes significantly to virulence after intracranial inoculation.²⁹³ Similarly, a comparison of vaccinia virus mutants inoculated either intranasally or in the pinna of the ear revealed that fully half of a panel of 16 different mutants had a phenotype in only one of the two inoculation models.²⁸⁵ Other examples of niche-specific virulence genes include herpesvirus genes associated with chronic infection or latency. These genes may be dispensable for the lytic phase of the life cycle but then play an essential role in promoting or maintaining the chronic stage of the viral infection. For example, γ HV68 viruses lacking either the *v-cyclin* or *v-Bcl-2* genes have limited or no phenotype during acute infection or in the establishment of latency.¹⁶ However, these genes play an important role in reactivation from latency and in the capacity to continuously replicate in immunocompromised mice. Therefore, when considering the function of a gene or virulence determinant *in vivo*, it is necessary to consider the limitations of the experimental system for revealing the role of a niche-specific viral gene.

Mutation and Selection of Viral Variants

Although viruses have niche-specific genes specialized for specific tasks *in vivo*, it is also possible for mutation and selection to meet specific needs during infection. For this reason, the error-prone RNA polymerases of viruses such as HCV and HIV play a role in viral pathogenesis. Viral RNA polymerases can make a mistake every 10^3 to 10^5 nucleotides while copying an RNA.^{59,60,65,223} In addition, point mutations, duplications, deletions, recombination events, and even acquisition of host mRNAs into RNA and DNA viral genomes have occurred in different viruses. Thus, the total mutational capacity of viruses is very high. It is plausible that a virus with a nearly 9,700-bp genome, such as HCV, will have a large number of mutations generated during replication even in a single cell. However, the variation actually observed *in vivo* or in serial passage in cultured cells is much lower than predicted from this argument. For example, comparison of the sequences of HCV over 13 years of infection of a single host revealed a mutation rate of 1.92×10^{-3} base substitution per genome site per year.²⁰³ Because the observed variation is low compared to the potential variation, it is plausible that the strength of the selective pressure applied to a viral population determines the nature of viruses present in the host at a given time. The capacity of mutation to provide the substrate on which selective pressure operates to generate new viral strains with altered pathogenic capacity has significant implications for understanding and controlling viral infections.

An excellent example of a mutation contributing to the pathogenesis of viral infection is the emergence of immune escape mutants. The principle that viral escape mutants can evade CD8 responses was first identified by study of murine LCMV infection.²²⁷ In this study, investigators created T-cell receptor transgenic (LCMV TCRtg) mice containing a large number of T cells specific for the epitope containing amino acids 32–42 of the LCMV glycoprotein. Within 8 days of infection, many LCMV isolates were no longer recognized by TCRtg T cells and contained mutations in the 32–42 epitope.²²⁷ Importantly, mutations in other T-cell epitopes that were not recognized by TCRtg T cells were not selected, indicating specificity of the selective pressure.

The relevance of this initial observation to events during infection in normal hosts is now well established.^{34,72,225} Both HIV and SIV accumulate mutations in CD8 T-cell epitopes over time, which is associated with progression of disease, escape from vaccine-mediated control of SIV infection, and escape from control of infection by adoptively transferred HIV-specific T cells.^{7,15,31,72,92,144,225} Similar observations have been made during chronic HCV infection, viruses such as MCMV develop mutations that enable escape from NK cell-mediated control, and genetic drift in seasonal influenza virus strains is in large part driven by selective pressure from antiviral antibodies.

Virus-Induced Immunosuppression

Virus infection is often associated with the induction of an immunosuppressed state. Immunosuppression is defined as a virus infection-associated decrease in the capacity of the immune system to respond to antigen. The phenomenon of immunosuppression was first noted as inhibition of tuberculin skin test reactivity during measles virus infection.^{95,96,187,218} That initial observation has been followed by a deluge of reports of altered immune reactivity in virus-infected hosts.

An immunosuppressed state may benefit a virus by inhibiting antiviral responses; however, it is important to distinguish between immunosuppression and viral immune evasion that occurs without inducing a general deficiency in immune function. It is also important not to confuse immunosuppression with the normal down-regulation of virus-specific responses that occurs as viral infection is cleared. There are three categories of immunosuppressive mechanisms.¹⁹⁴ In the first, virus kills significant numbers of critical immune system cells; an example of this is HIV-associated depletion of CD4 T cells. Likewise, LCMV clone 13 causes immunodeficiency owing to destruction of DCs that are critical antigen-presenting cells. In this case, activated CD8 T cells that recognize viral antigens expressed by infected DCs damage the immune system.^{8,30,158,324} A second potential mechanism involves alterations in cytokine secretion by infected cells or the induction of secreted molecules that inhibit immune responses. This mechanism, however, does not provide a clear explanation for a case in which immunosuppression persists long after infection is thought to be cleared. A third but largely speculative potential mechanism only now being explored is viral induction of regulatory T cells that may inhibit the immune response.

Viral Evasion and Subversion of Host Cytokine Responses

Host molecules present in the extracellular fluid including cytokines, prostaglandins, steroid hormones, peptide hormones, growth factors, and serum components such as complement provide important targets for viral evasion and subversion strategies. Viruses encode molecules that evade or subvert host hormonal and cytokine responses that regulate both innate and adaptive immunity, such as interferons, TNF, IL18, IL6, IL10, complement, and chemokines. These viral evasion and subversion molecules have been studied in detail for herpesviruses and poxviruses, including via the use of viral mutants lacking these proteins to determine their specific role *in vivo*.

The remarkable sophistication of viral cytokine evasion proteins is exemplified by the structure of the γ HV68 chemokine-binding protein M3, which alters the inflammatory response to viral infection^{6,293} (Fig. 10.12). Chemokines are a large group of polypeptides that regulate immune cell trafficking, cell differentiation, and tissue development. The M3 protein has evolved to mimic both the chemokine receptor of the host and the dimer interface between chemokines as a way to bind a broad array of chemokines with a very high affinity. It is likely that similar molecules and mechanisms will be discovered in other viruses and that additional host cytokine systems will be discovered that are targeted by viral immune evasion and/or subversion molecules. In addition, viruses can increase inflammation to foster infection and can induce tissue damage via paracrine effects of virus-infected cells.

Virus–Host Co-Evolution Drives the Host–Pathogen Interaction

The interactions between viral immune evasion proteins in host cytokine networks are highly sophisticated. Given this capacity to manipulate the host, one may question why viruses are not more virulent. A common belief is that the most dangerous and virulent viruses are those that have recently jumped from one species to another—the idea being that virulence *per se* can be the result of incomplete adaptation of the virus to the host. Implicit in this view of viral pathogenesis and evolution is the

A Characterize pathogenesis of M3 mutant**B** Lethality**C** Cellular infiltrate in meninges**D** M3:MCP-1 complex**E** Contact surfaces between M3 and MCP-1**FIGURE 10.12. Role of a viral chemokine-binding protein in herpesvirus pathogenesis.**

A: Experimental protocol for analysis of the pathogenesis of an M3 mutant in murine γ HV68 derived from reference 293. **B:** Lethality observed at different doses of virus administered intracranially. *Marker rescue* refers to a control virus generated by restoring wild-type γ HV68 sequences to the M3 mutant virus. **C:** The nature of the meningeal cellular infiltrate of mice infected with the indicated viruses. Note that inflammation induced by the M3 mutant virus shows increased macrophages and decreased neutrophils compared to wild-type and control viruses. **D:** Three-dimensional structure of M3 homodimer (solid) in complex with the chemokine MCP-1 (tubes) bound at either end of the M3 homodimer in a 2:2 stoichiometry. Note that the M3 dimer is arranged in an antiparallel fashion with the M3 N- and C-terminal domain packed together to form the chemokine-binding niche. **E:** The interfaces between M3 and MCP-1 are shown in more detail than in D. M3 chemokine-binding regions are shown as tubes, whereas the sequestered MCP-1 is depicted with its solvent accessible surface. M3 acts as a competitive inhibitor of chemokine function, shown here engaging the same interface of MCP-1 employed to bind the host chemokine receptor CCR2. (D and E adapted from Alexander JM, Nelson CA, van Berkel V, et al. Structural basis of chemokine sequestration by a herpesvirus decoy receptor. *Cell* 2002;111:343–356; courtesy of Drs. Jennifer Alexander-Brett and Daved Fremont.)

concept that viruses benefit from adapting to lesser virulence. Examples of the virulence of viruses that have recently entered a new host population abound, with the influenza pandemic of 1918, Ebola virus, and HIV being outstanding examples. Each of these virulent viruses has entered humans from another species and is more virulent in the newly invaded species than in the original host species.

What really happens to the virus and the host species as an emergent virus spreads? In a classic series of experiments analyzing the epidemiology, pathogenesis, and virology of myxomatosis in rabbits, Fenner et al. demonstrated virus–host co-evolution. The natural history and evolution of both a virus and its host were followed in real time after the introduction of a virulent virus into a highly susceptible population. Importantly, although both the host and virus evolved in this enormous experiment of nature, this work does not support the concept that viruses necessarily evolve to become completely avirulent in a new species.

The introduction of European rabbits into Australia by European settlers provided the substrate for both an ecological disaster and a series of fundamentally important experiments in viral pathogenesis. Absent natural predators, European rabbits expanded rapidly in Australia with severe ecological

consequences, creating a need for a pest control strategy. Myxomatosis is a relatively benign disease in *Sylvilagus* rabbits from South America but is almost uniformly lethal in the European rabbit *Oryctolagus*.^{74,76} Recognizing that an infection that spread quickly and killed rabbits might be an effective biological weapon, investigators released myxoma virus into the Australian rabbit population in 1950. Initially, the kill rate was calculated as 99.4% to 99.8%, with most surviving rabbits being uninfected.

Over the next several years, a remarkable process of evolution of both the virus and the rabbit host occurred and was experimentally documented.^{76,77} Similar evolution of the rabbit host was observed in laboratory experiments.²⁶² Over the course of a single year, the virus became less virulent, killing only 90% of laboratory European rabbits⁷⁴ (Table 10.1). It is hypothesized that this initial decrease in virulence allowed enough rabbits to survive and breed to allow selection of rabbits capable of resisting virulent myxoma. The virulence of isolates was categorized into five classes, with grade 1 killing more than 99% of rabbits and grade 5 killing less than 50% of rabbits^{74,77} (see Table 10.1). By 1975, less than 2% of isolates were highly virulent class I viruses, whereas more than 60% of isolates were class III viruses. Notably, the distribution of isolates with

differing virulence was relatively stable from about 1955 onward, indicating that equilibrium between rabbit and virus was established. The rabbit population similarly evolved. Whereas wild rabbits initially exhibited more than 90% lethality when challenged with a virulent isolate of myxoma virus, after multiple epidemics only 30% of challenged rabbits died and 46% suffered mild to moderate disease (Table 10.2).

Given this evidence for evolution toward resistance in the rabbit population and toward lower virulence in the virus, why didn't myxomatosis become a benign disease in European rabbits? Evolution of the virus to lower virulence, but not avirulence, occurred (see Table 10.1). There were other selective pressures at work in this evolutionary experiment. Field experiments showed that virulent viruses were at a disadvantage compared to less virulent naturally occurring isolates.⁷⁴ Even when virulent isolates were introduced into areas in which attenuated viruses were

endemic, the attenuated viruses were dominant. Very virulent viruses plausibly were at a disadvantage as they killed their hosts rapidly, allowing less time for natural transmission by mosquitoes. Thus, the capacity to persistently infect some hosts or to slow the infectious process might have fostered the capacity to infect new hosts over longer periods, thereby providing a selective advantage. However, the virus had to spread efficiently to survive, and experiments showed that viruses with midrange virulence were present in skin at sufficient levels to spread via mosquitoes. It is believed that selective pressure retained a level of virulence associated with replication to high enough levels to spread,⁷⁴ explaining why the outcome was not evolution to avirulence.

Virus Genes That Inhibit Pathogenesis of Disease

It is a common misconception that viruses primarily encode molecules to cause disease. Although retention of some level

of virulence during adaptation within a host species can be an advantage, evolution to lower virulence did occur in the example presented earlier.^{74,197} One way to lose virulence would be to sequentially lose or inactivate virulence genes or determinants. A second nonexclusive mechanism would be to select for genes that actually protect the host from lethal infection—a prediction borne out by studies of vaccinia virus showing that some viral genes protect their hosts from virus-induced disease.^{4,5} Vaccinia virus expresses a secreted IL-1 β receptor homolog that neutralizes the effects of IL-1 β . Although this gene might plausibly contribute to virulence, instead a mutant virus induced fever and the wild-type virus did not despite similar levels of replication (Fig. 10.13).⁵ The fever induced by the mutant virus was attributed to IL-1 secretion by the host because anti-IL-1 antibody blocked fever induced by the mutant virus (see Fig. 10.13). Expression of the soluble IL-1 β receptor also decreased clinical signs of illness and decreased weight loss. Repair of a nonsense mutation in the soluble IL-1 β receptor in a vaccine strain of vaccinia resulted in a virus that did not induce fever. These data demonstrate that protection of the host can be an active result of viral gene expression rather than a passive process of loss of virulence factors, suggesting that viruses have the capacity to precisely balance virulence and avirulence strategies to foster their survival.

FUTURE OF VIRAL PATHOGENESIS RESEARCH

The study of viral pathogenesis promises to be as important in the future as it has been in the past for understanding fundamental biological and biochemical mechanisms of disease.

Understanding the process of infection is increasingly recognized as the best, and perhaps the only, approach to understanding how to vaccinate against and treat severe unconquered infections such as HIV and HCV and emerging viruses such as Ebola and H5N1 bird influenza. New developments in human genomics combined with ever-improving methods for manipulation of both viral and host genomes will continue to accelerate progress in this critical field of biology. The progress made in other fields as unbiased genetic screens are applied to cell biological problems is breathtaking. In recent years, we have seen the application of these approaches to virology, where whole genome RNA interference (RNAi) screens provide new insights into which host genes are essential for viral replication. Similar approaches are now being applied to identify antiviral and viral restriction factors that regulate the control, tissue tropism, and host range of a wide range of viruses. To date, many of these approaches have been restricted to cell culture-based studies; however, the broadening availability of large panels of genetically modified mice, including knockout and transgenic animals, should continue to facilitate major advances in viral pathogenesis from the standpoint of virus–host interactions.

We have also seen unprecedented progress in our ability to perform studies in genetically complex populations, including the use of GWAS and whole exome and whole genome sequencing to identify polymorphic host genes that are associated with specific phenotypes, including susceptibility to viral infection. The application of these approaches in humans, as well as newly developed mouse models designed to model genetically diverse populations, to the study of viral pathogenesis is likely to revolutionize our understanding of how viral interactions with genetically diverse populations result in different pathogenic outcomes.

Related to these latter approaches, the power of mathematical methods for modeling complex phenomena is improving rapidly and will ultimately be applied to viral pathogenesis. It will be important to apply these tools with a rigorous understanding of the clinical context of disease and an awareness of both the benefits and limitations of studying viral infection in the live host. *In vivo veritas*.

Although Charles Darwin preempted many of the great questions in evolutionary biology, he wrote little about viral infections. Of course, viruses were not formally identified until a full decade after Darwin's death, and, aside from some brief discussion of the origins of yellow fever, his writings make scant reference to what we now know are diseases caused by viruses. This is a great historical shame because it seems certain that Darwin would have held viruses up as some of the best exemplars of evolution by natural selection, and in the case of RNA viruses the evolutionary process is so rapid that it can be effectively followed in "real time".^{123,204}

Although evolutionary analysis arrived relatively late in the science of virology, the study of virus evolution has become one of the most rapidly growing and successful aspects of modern microbiology. The blossoming of evolutionary virology is largely due to two developments. First, viruses, and especially those that possess RNA genomes, have become remarkably powerful research tools for the study of evolutionary processes. The utility of RNA viruses in this respect is a function of the fact that they evolve extremely rapidly, are easy to manipulate *in vitro* and sometimes *in vivo*, often have large and measurable effects on phenotype, and possess such small genomes that the mutations

associated with any phenotype change can be determined relatively easily.⁶⁰ It is therefore no surprise that a growing number of evolutionary researchers are turning to viruses as model systems. For example, studies of viruses represent one of the few cases in which biologists have been able to achieve two of the great aims of modern evolutionary genetics: to measure the fitness effects of individual mutations¹⁹⁵ and to determine the nature of the epistatic interactions between these mutations.¹⁹⁷ Second, the rapidity of RNA virus evolution has acted as a direct stimulus for the development of phylogenetic and coalescent methods that are able to incorporate information on the exact time of sampling of the sequences in question, in turn revolutionizing molecular epidemiology.^{49,132} Indeed, many of the computer programs designed for the evolutionary analysis of gene sequence data were first applied to viruses, such that determining the origin and pathways of spread of specific viruses over epidemiologic time has become a relatively exact science with a myriad of potential applications. The advent of next-generation sequencing promises even more rapid advances in this area, potentially enabling the analysis of many thousands of sequences with detailed associated metadata.⁹⁵ An important spinoff from these studies has been new insights into the patterns and processes of virus evolution.^{79,92} In sum, although their focus is very different, the combination of experimental analyses of model viruses as a means to understand the intricacies of the evolutionary process and studies of molecular epidemiology based on the comparative analysis of virus gene sequence data to document patterns of virus spread has told us a great deal about the nature of virus evolution. Evolutionary virology has blossomed into a well-developed science.

Despite advances on multiple fronts, some fundamental aspects of viral evolution remain unknown, contentious, or both, which will be highlighted in this chapter. For example, there are still major debates over some of the key mechanisms of evolutionary change in RNA viruses, particularly whether their populations routinely form quasispecies, which reflects a wider uncertainty on the roles of mutation, natural selection, and genetic drift as forces of evolutionary change.⁹² For example, it is striking that precise estimates of mutation rates are absent from some important groups of viruses even though they represent a sort of "ground zero" in studies of evolutionary change. Similarly, although we know a great deal more about the origin of viruses than we did 10 years ago, particularly since the discovery and analysis of highly conserved protein structures, exactly when and how viruses first evolved, whether this occurred before or after the appearance of the first cellular organisms, what a precellular world might have looked like, and even if viruses should be classified as living are sources of major debate.^{71,121,138,159} In part, this debate highlights our

profound ignorance of the virosphere. For example, does the apparent absence of RNA viruses in *Archaea* mean that they never existed in these species, that they have been selectively removed, or that we have simply not looked hard enough? Another important issue is that in some respects our knowledge of DNA virus evolution lags behind what we know of the evolution of RNA viruses. We remain ignorant of a number of key aspects of the patterns and processes of DNA virus evolution, particularly whether common principles can be applied to DNA viruses that differ so greatly in size and genome structure. It is hoped that the rise of metagenomics, such that we will sample far more of the virosphere, likely leading to the discovery of a multitude of diverse viruses, will stimulate many advances in this area. Finally, the time scale of evolutionary history in many viruses is unclear, with very different inferences drawn from either the study of endogenous viruses, which are usually indicative of ancient origins, or the molecular clock analysis of recently sampled and often rapidly evolving viral genomes, which usually paints a picture of very recent origins.^{80,94} Advances in this area may require the development of a new class of analytical methods.

Aside from their ability to inform on evolutionary processes, there are a number of practical reasons that the study of virus evolution deserves attention. It is likely that a better understanding of the exact processes of evolutionary change in viruses will assist in the development of improved strategies for their treatment and control and for predicting the spread of newly emerged pathogens. For example, knowing whether natural selection or genetic drift largely controls how mutations spread through a population is essential to understanding the likelihood and rate that a specific drug resistance mutation will become established,¹³¹ while a knowledge of the factors that control how viruses diffuse at the epidemiologic scale represents useful information for any emergent virus.⁹⁵ Similarly, it is likely that a better understanding of the origin of viruses will be essential to obtaining a more precise picture of the earliest events in the early history of life on earth, including the genesis of both RNA and DNA, as it seems reasonable to suppose that some of the earliest replicators resemble what we now know as viruses.

The future of evolutionary virology appears strong. The development and continued refinement of next-generation sequencing methods will doubtless provide unprecedented amounts of data for evolutionary study and stimulate the development of new analytical methods for use in all genetic systems. Innovations in experimental studies of virus evolution will continue, addressing ever more intricate questions, increasingly considering *in vivo* systems, and providing broad-scale evolutionary insights. Metagenomic studies of the virosphere will provide a powerful new perspective on virus biodiversity, in turn bringing important new information on virus ecology, origins, and cross-species transmission and emergence. It therefore seems easy to predict that our understanding of viral evolution 10 years from now will be very different, and more complete, than it is today.

THE ORIGIN AND TIME SCALE OF VIRUS EVOLUTION

The Origins of Viruses

Of all topics in the study of virus evolution, determining exactly how and when viruses first evolved is perhaps the most

difficult. The main hindrance to progress in this area is that viruses likely originated so long ago, and perhaps even before the first cellular species, that the signal of ancient evolutionary history that can be recovered through phylogenetic analysis has largely been eroded. This is particularly true for RNA viruses where rapid rates of evolutionary change ensure that the phylogenetic signal is quickly lost. Accordingly, each individual amino acid and nucleotide site in a viral genome has accumulated so many substitutions since its origin that accurate phylogenetic inference becomes an impossible task. For this reason sequence-based phylogenies have proven to be blunt tools for the study of viral origins, although signs of common ancestry may still reside in aspects of protein structure.

Despite the inherent limitations to understanding viral origins, a number of important theories have been proposed for the genesis of both RNA and DNA viruses, which continue to be debated to this day. Currently two such theories dominate discussions in this area; first, that viruses have a precellular origin, such that they are billions of years old, and may have even contributed to some of the fundamental architecture of the first cells; second, that viruses evolved after the first cellular organisms as “escaped genes” that acquired capsid proteins and the ability to replicate autonomously (Fig. 11.1). Although a third hypothesis—that viruses are regressed copies of cellular species that have shed those genes whose functions are provided by the host—has also been proposed, most notably in the case of the giant mimivirus and megavirus of amoeba,^{9,128} it does appear to be of general applicability. For example, the gene contents of RNA viruses and cellular species have almost no overlap, whereas under the regressive theory virus genes should have their ancestries in cellular genomes. In addition, although often discussed as such, these theories of viral origins are not mutually exclusive, and it is plausible that while some viruses predate the appearance of the first cells, others appeared more recently.

For many years the escaped gene theory dominated discussions on virus origins.¹⁶⁰ Support for this theory was often based on the idea that as viruses are obligate parasites of host cells now, they must have always been so in the past, such that cells must have evolved before viruses. However, this idea is easy to refute. Because it is commonly thought that the first replicating molecules resided in an “RNA world” that existed before the evolution of DNA, it is easy to believe that modern RNA viruses originated from such ancient self-replicating RNA molecules and parasitized cells at a later date. Important recent evidence for the existence of an RNA world was the demonstration that ribonucleotides could be synthesized *de novo* under conditions that might replicate those of early earth.¹⁷⁹ In most cases the escaped gene theory was also taken to mean that viruses could have escaped from host cells on multiple occasions. This is an attractive idea given the huge phenotypic diversity seen in viruses and that there is no one gene that characterizes all viruses. For example, an early idea was that eukaryotic viruses had escaped from eukaryotic cells, while bacteriophages had escaped from bacterial cells.¹⁸⁰ Similarly, it is possible that RNA, DNA, and perhaps retroviruses represent independent episodes of host gene escape, as could the single- (ss) and double-stranded (ds) versions of RNA and DNA viruses, particularly as small ssDNA and large dsDNA viruses clearly have little in common.

However many different origins are postulated, the same general mechanisms are thought to have occurred: that a host

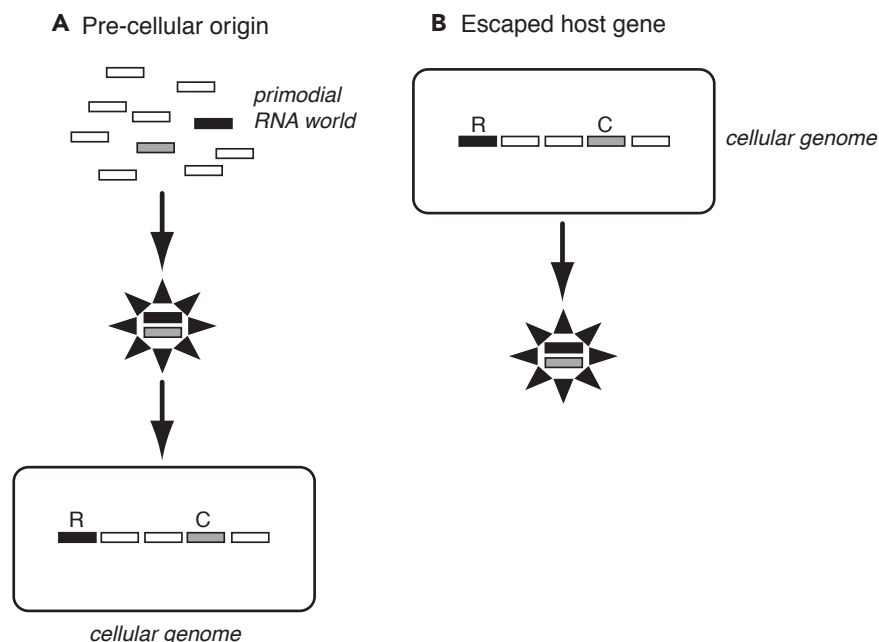

FIGURE 11.1. Schematic representation of two competing models for the origin of viruses. **A:** The precellular origin theory (in this case depicting the origin of RNA viruses). **B:** The escaped gene theory. Cellular genomes are represented by rounded rectangles, and the simplest model virus is shown here to comprise replicase (R) and capsid (C) genes only. (From Holmes EC. *The Evolution and Emergence of RNA Viruses*. Oxford: Oxford University Press, 2009, by permission of Oxford University Press.)

gene that possessed or acquired the ability to self-replicate escaped from the cell, acquiring a protein coat on the way, eventually evolving into an autonomously replicating entity. For example, single-strand positive-sense RNA (ssRNA+) viruses might be descended from escaped cellular messenger RNA (mRNA) molecules that either possessed or evolved RNA polymerase activity, while DNA viruses could be descended from DNA transposable elements or bacterial plasmids. It is also the case that all forms of the escaped gene theory make two important predictions: first, that most virus genes, including the capsid and replicase proteins, ultimately have their ancestries in cellular genomes, and second, because escape events could have occurred multiple times, viruses do not have a single (i.e., monophyletic) origin. In other words, there is no single phylogeny linking all types of virus, as is easily argued from the huge diversity of viruses described today. In theory, both of these predictions are testable, although in practice this is greatly inhibited by the enormous sequence divergence among viruses.

A number of pieces of data have been used to support the idea that viruses had multiple origins after the appearance of cells. At the level of primary amino acid sequence, there is no robust sequence-based phylogeny for either RNA or DNA viruses, nor any gene that contains statistically significant sequence similarity at such vast evolutionary distances. Although there have been attempts to infer the evolutionary history of RNA viruses based on phylogenetic analyses of the RNA-dependent RNA polymerase (RdRp), the phylogenies in question are highly uncertain at the interfamily level where there is often no more sequence similarity than expected by chance alone.^{92,236} However, lack of phylogenetic resolution is not the same thing as an absence of common ancestry, and it is more likely that the inability to accurately infer the evolutionary history of all RNA viruses simply reflects extreme levels of sequence divergence. Indeed, it is striking that the RdRp sequences assigned to different RNA virus families still share a number of short, signature, amino acid motifs (such as a highly

conserved GDD motif), some of which are also found in the reverse transcriptase (RT) protein used by retroviruses.^{81,120} Such conservation, albeit fragmentary, suggests that these replicatory proteins are distantly related. Unfortunately, these motifs are too short to allow the inference of reliable phylogenetic trees. Even more notable is that recent analyses of protein structure have revealed strong similarities between viruses that exhibit no primary sequence similarity, including between RNA and DNA viruses (see later).

In the case of RNA viruses, early phylogenetic analyses of RdRp sequences combined with information on gene order and content were used to construct *supergroup* classification schemes encompassing multiple viral families. For example, one such study suggested that RNA viruses be classified into the alpha-like, carmo-like, corona-like, flavi-like, picorna-like, and sobemo-like supergroups, each of which is characterized by a conserved gene order, distinctive 5' and 3' genome structures, as well as a putative clustering in RdRp phylogenies.⁸¹ However, as noted earlier, extreme sequence divergence means that these RdRp phylogenies are of debatable validity,²³⁶ and it is difficult to construct trees on gene order and content when these differ so dramatically among viral families and in genomes as small as those of RNA viruses. As a consequence, these deep interfamily phylogenies have in reality told us little about virus origins. However, a number of higher-order viral groupings, usually referred to as *orders*, do receive strong phylogenetic support, such that some aspects of the early evolutionary history of RNA viruses can be resolved. These groupings are (a) the *Mononegavirales*, which comprises four families of unsegmented ssRNA– viruses—the *Bornaviridae*, *Filoviridae*, *Paramyxoviridae*, and *Rhabdoviridae* (and the *Mononegavirales* clearly cluster together in RdRp trees); (b) the *Nidovirales*, comprising the *Arteriviridae*, *Coronaviridae*, and *Roniviridae* families of ssRNA+ viruses; and (c) the *Picornavirales*, comprising the *Picornaviridae*, *Comoviridae*, *Dicistroviridae*, *Marnaviridae*, and *Sequiviridae* families of ssRNA+ viruses.

Interfamily phylogenetic analyses of DNA viruses have generally proven more successful, in large part because the reliance on high-fidelity DNA polymerases for replication means that dsDNA viruses exhibit lower rates of nucleotide substitution and hence preserve the phylogenetic signal for longer time periods. For example, a number of families of large dsDNA viruses (i.e., those with genomes greater than 100 kb) clearly possess common ancestry such that they can be classified as nucleocytoplasmic large DNA viruses (NCLDVs), comprising ascoviruses, asfarviruses, iridoviruses, phycodnaviruses, and poxviruses.¹⁰⁴ More recent analyses extended the NCLDV group to include the giant amoebal mimivirus, which is most closely related to the phycodnaviruses,¹⁰⁵ as well as the recently described Marcellvirus, which was isolated from the same amoebal host as mimivirus.²³⁵ In other DNA viruses elements of capsid protein structure have been used to link herpesviruses with tailed bacteriophages,¹⁴⁹ while there are clear evolutionary links between the *Papillomaviridae* and *Polyomaviridae* families of small dsDNA viruses.²³² However, there is no phylogeny that encompasses both single- and double-stranded DNA viruses, which again reflects the great divergence between these very different types of virus (which differ massively in genome size) that share no genes in common. More starkly, it is even difficult to infer phylogenetic trees that link all the large dsDNA viruses that infect eukaryotes.¹⁰⁵

The second prediction of the escaped gene theory—that most virus proteins ultimately have a host origin—is equally difficult to resolve. The two most important proteins in this respect, as they essentially define viruses, are the polymerase (a defining feature of all RNA viruses that carry an RdRp or RT) and those that make up the capsid (a defining feature of viruses). The case of the DNA polymerases used by DNA viruses is the easiest to discuss in this context as these enzymes are of the same form, and hence ancestry, as those used by cellular species (i.e., they are classified within the same polymerase families), and small DNA viruses utilize the host DNA polymerases for replication. However, while it is clear that these host and virus DNA polymerases are related,^{65,103} the position of the root, and therefore the direction of evolutionary change, in phylogenetic trees of DNA polymerases is uncertain. Hence, it is difficult to determine whether DNA polymerases are ultimately of host or viral origin,²⁰⁰ particularly as DNA polymerases may also have been involved in ancient lateral gene transfer events.⁶⁵

A similar discussion can be mounted in the case of reverse transcriptase. Proteins that function as reverse transcriptase are a common component of cellular genomes in the form of telomerase, the group II (self-replicating) introns observed in a variety of bacterial species, not to mention the abundant retroelements found in many cellular species, as well as a variety of other genetic elements. Importantly, there are recognizable sequence similarities between the RTs of viruses and those that reside in host genomes such that it is possible to infer phylogenetic trees containing both.^{32,54} These trees have revealed a number of interesting features, including a major division between the long terminal repeat (LTR) and non-LTR retrotransposons, with retroviruses most closely related to the LTR retrotransposons, and that hepadnaviruses and caulimoviruses (small dsDNA viruses that utilize RT) have independent origins and are probably from LTR retrotransposons. However, as with the case of the DNA polymerases, the lack of an outgroup makes the rooting of these phylogenies uncertain, so whether

viral RT genes preceded those present in cells or vice versa is difficult to determine.⁵⁵

The situation is far more complex when it comes to the origin of the RdRp used by RNA viruses. Although the cells of some eukaryotic species contain proteins that function as RdRps, particularly those involved in the production of microRNAs, these exhibit little similarity with the RdRps encoded by viruses, even at the structural level.¹⁰⁶ Similarly, cellular DNA polymerase (Pol) II, which catalyzes the synthesis of RNA from DNA, possesses RdRp activity¹³⁰ yet shares little similarity with the RdRp utilized by RNA viruses, such that their evolutionary origins are currently impossible to resolve. Clearly, determining the evolutionary relationships among these highly diverse polymerase proteins represents a major technical challenge.

While the evidence from phylogenetic trees is ambiguous at best, other pieces of data do provide some support for the escaped gene theory. The most compelling of these is that there is at least one example of a virus whose origins likely lie with a host cellular protein, demonstrating that this mode of viral genesis is possible. The case in point involves hepatitis delta virus (HDV) agent, the ribozyme of which is related to the CPEB3 ribozyme found in a human intron sequence.¹⁹² That HDV is only found in humans and requires hepatitis B virus (HBV) for replication strongly suggests that its origins lie with the human genome.¹⁹²

There has also been considerable debate over the significance of the giant amoebal mimivirus for theories of viral origins and evolution. Although phylogenetic analysis has shown that a small proportion (less than 1%) of mimivirus genes are of host origin, which has been used as support for the idea that viruses are “gene pickpockets” that originated after cellular species,^{158,159} at least 25% of the approximately 1,000 genes in mimivirus clearly link it to the NCLDV group of large DNA viruses,¹⁰⁵ while an even larger set of genes (~70% at the time of writing) have no known homologs, in either viral or cellular genomes, such that they can be regarded as orphans.⁶⁴

Finally, it is striking that, at the time of writing, no RNA viruses have been discovered in *Archaea*. This could mean that either RNA viruses arose as escaped genes after the divergence of *Archaea* from other cellular species or that temperature constraints have led to a major reduction in the frequency of RNA viruses in hyperthermophilic *Archaea*,²³⁷ although this does not explain their absence in nonthermophiles. An alternative, and perhaps more likely, explanation is that RNA viruses do exist in *Archaea* but have simply not been detected as yet.

The competing theory for the origin of viruses, and one that is growing in popularity, is that they originated before the last universal cellular ancestor (LUCA) and represent the modern descendants of the earliest time in earth's history. Hence, modern RNA viruses would be descendants of replicating elements from the RNA world, while DNA viruses would be remnants of the first DNA replicators, and retroviruses perhaps descendants of the first molecules that made the transition from RNA to DNA. For example, because they lack protein-coding regions, possess ribozyme activity, exhibit complex secondary structures, and mutate very rapidly, viroids are potential candidates for extant descendants of the RNA world.⁵⁹ However, although the earliest RNA replicators may share some features with contemporary viroids, because viroids are only seen in plants and likely replicate with the assistance of host cellular

DNA Pol II makes it more likely that they represent escaped host genes or introns that never acquired protein coats.

There are a number of theories for what the pre-LUCA world may have looked like, although all reasonably assume that this precellular stage of evolutionary history contained genetic elements less complex than the viruses we see today. One theory is that there was an *ancient virus world* of primordial replicators that existed before any cellular organisms and that both RNA (first) and DNA (later) viruses originated at this time.¹²¹ A version of this view of virus origins is shown in Figure 11.2. These ancient “viruses” may even have provided some of the features that characterized the first cellular organisms. For example, it has been proposed that the eukaryotic cell nucleus is derived from a virus envelope (the so-called viral eukaryogenesis hypothesis).¹³ An alternative theory for the pre-LUCA world is that RNA cells existed before the LUCA, that RNA viruses parasitized these hypothetical RNA cells, and that DNA evolved later as a way of escaping host cell responses.⁷⁰ Although fascinating, such theories are unfortunately extremely difficult to test.

As sequence-based phylogenetic trees cannot provide insights into the pre-LUCA world, the main evidence for the precellular theory of virus origins is the presence of conserved genes, and more notably protein structures, among divergent viruses. In fact, arguably one of the most important advances in viral evolution in recent years has been the discovery of protein structures that are conserved among diverse viruses that possess little, if any, primary sequence similarity.¹¹ For example, a conserved palm subdomain protein structure, consisting of a four-stranded antiparallel β -sheet and two α -helices, is found in both RNA-dependent and DNA-dependent polymerases.⁸⁴ A more important case in point concerns the jelly-roll capsid, a tightly structured protein barrel that forms the major capsid subunit of virions with an icosahedral structure. Remarkably, the jelly-roll capsid is found in the virions of both RNA and DNA viruses, including such diverse groups as herpesviruses (dsDNA), picornaviruses (ssRNA+), and birnaviruses (dsRNA).^{11,41} Such conservation is strongly suggestive of an ancient common ancestry. Other highly conserved capsid architectures that strongly argue for ancient origins include the PRD1-adenovirus lineage, which is characterized by a double β -barrel fold and found in dsDNA viruses as diverse as bacteriophage PRD1, human adenovirus, and a variety of archaean viruses; the BTV-like lineage, which is found in some dsRNA viruses including members of the *Reoviridae* and *Totiviridae*; and the HK97-like lineage, which encompasses tailed dsDNA viruses that infect archaea, bacteria, and eukaryotes.^{16,17,124} Finally, a common virion architecture has been proposed for some viruses that do not possess an icosahedral capsid, including the archaean virus *Halorubrum* pleomorphic virus type 1 (HRPV-1).¹⁷⁶

Although such structural conservation seems to provide a compelling argument for the antiquity of viruses, it has been proposed that any similarities in protein structure could have arisen more recently due to either strong convergent evolution or lateral gene transfer.¹⁵⁹ While it is theoretically possible that convergent evolution may occur relatively frequently in viral capsid proteins that may be subject to strong selection to be small and perhaps of a specific shape, such large-scale convergence seems highly unlikely given that the similarity in capsid structure covers a huge range of viral taxa. As a consequence, multiple

convergent events need to be invoked from very different starting points, and the more convergent evolution that is required, the less likely it becomes. Frequent lateral gene transfer also seems unlikely. As noted later, current data suggest that lateral gene transfer is relatively rare in RNA viruses (although commonplace in large DNA viruses), in large part because of major selective pressures against the expansion of genome sizes.⁹² As the earliest replicating RNAs likely possessed higher error rates than those of contemporary RNA viruses, the first genomes would have been even more restricted in size, such that lateral gene transfer without exact gene replacement must also have been uncommon at this time. Hence, although DNA viruses may be habitual gene pickpockets, RNA viruses do not seem to be. In conclusion, while not conclusive, the presence of structural similarities among highly divergent viruses currently constitutes the strongest evidence that viruses have a precellular origin.

The Time Scale of Virus Evolution

As our understanding of viral origins is vague, so is our knowledge of the antiquity of those families of viruses that circulate today, in part because viruses lack any sort of fossil record. In general, there are three ways in which the evolutionary history of viruses can be placed on a chronological scale. First, if there is a strong match between the phylogenetic tree of viruses and that of their hosts, such that they have *co-diverged*, then it is possible to use the divergence times of hosts to calibrate the time scale of virus evolution. Second, for viruses that evolve rapidly such that there is *measurable evolution* (i.e., mutations are fixed in viral populations during the time frame of human observation), which has been clearly demonstrated in both RNA viruses and ssDNA viruses, it is possible to determine the number of substitutions that have occurred between viruses sampled at known times (heterochronous samples) and use this information to calibrate the time scale of virus evolution under the assumption of a molecular clock (i.e., that there is an approximately constant rate of nucleotide or amino acid fixation). Third, for viruses where endogenous genome copies are present in the host, it is possible to use the substitution rate of the host to determine when these genome integration events occurred, especially if the endogenous sequences also co-diverge with their host species. All three approaches have limitations and can lead to wildly different interpretations of evolutionary time scales, the resolution of which has yet to be achieved.

Dating the time scale of virus evolution through the use of host divergence times (i.e., co-divergence) is perhaps the simplest and most robust approach to this form of molecular archaeology. This approach has been particularly successful in the study of DNA virus evolution. Good examples of its utility are the dating of herpesvirus evolution through an examination of the phylogenetic relationships of their vertebrate hosts, in which virus–host co-divergence may extend to some 400 million years^{148,149}; of the animal iridoviruses¹⁰⁷; of the baculoviruses of insects⁹⁰; and of the papillomaviruses sampled from a number of vertebrates including humans.¹⁹ Clearly, although each of these virus families can be considered as “ancient,” they are in no way of sufficient age to inform on the question of virus origins. In addition, in some other large DNA viruses, with the poxviruses a good example, frequent host-jumping means that patterns of host–virus co-divergence can be difficult to infer,

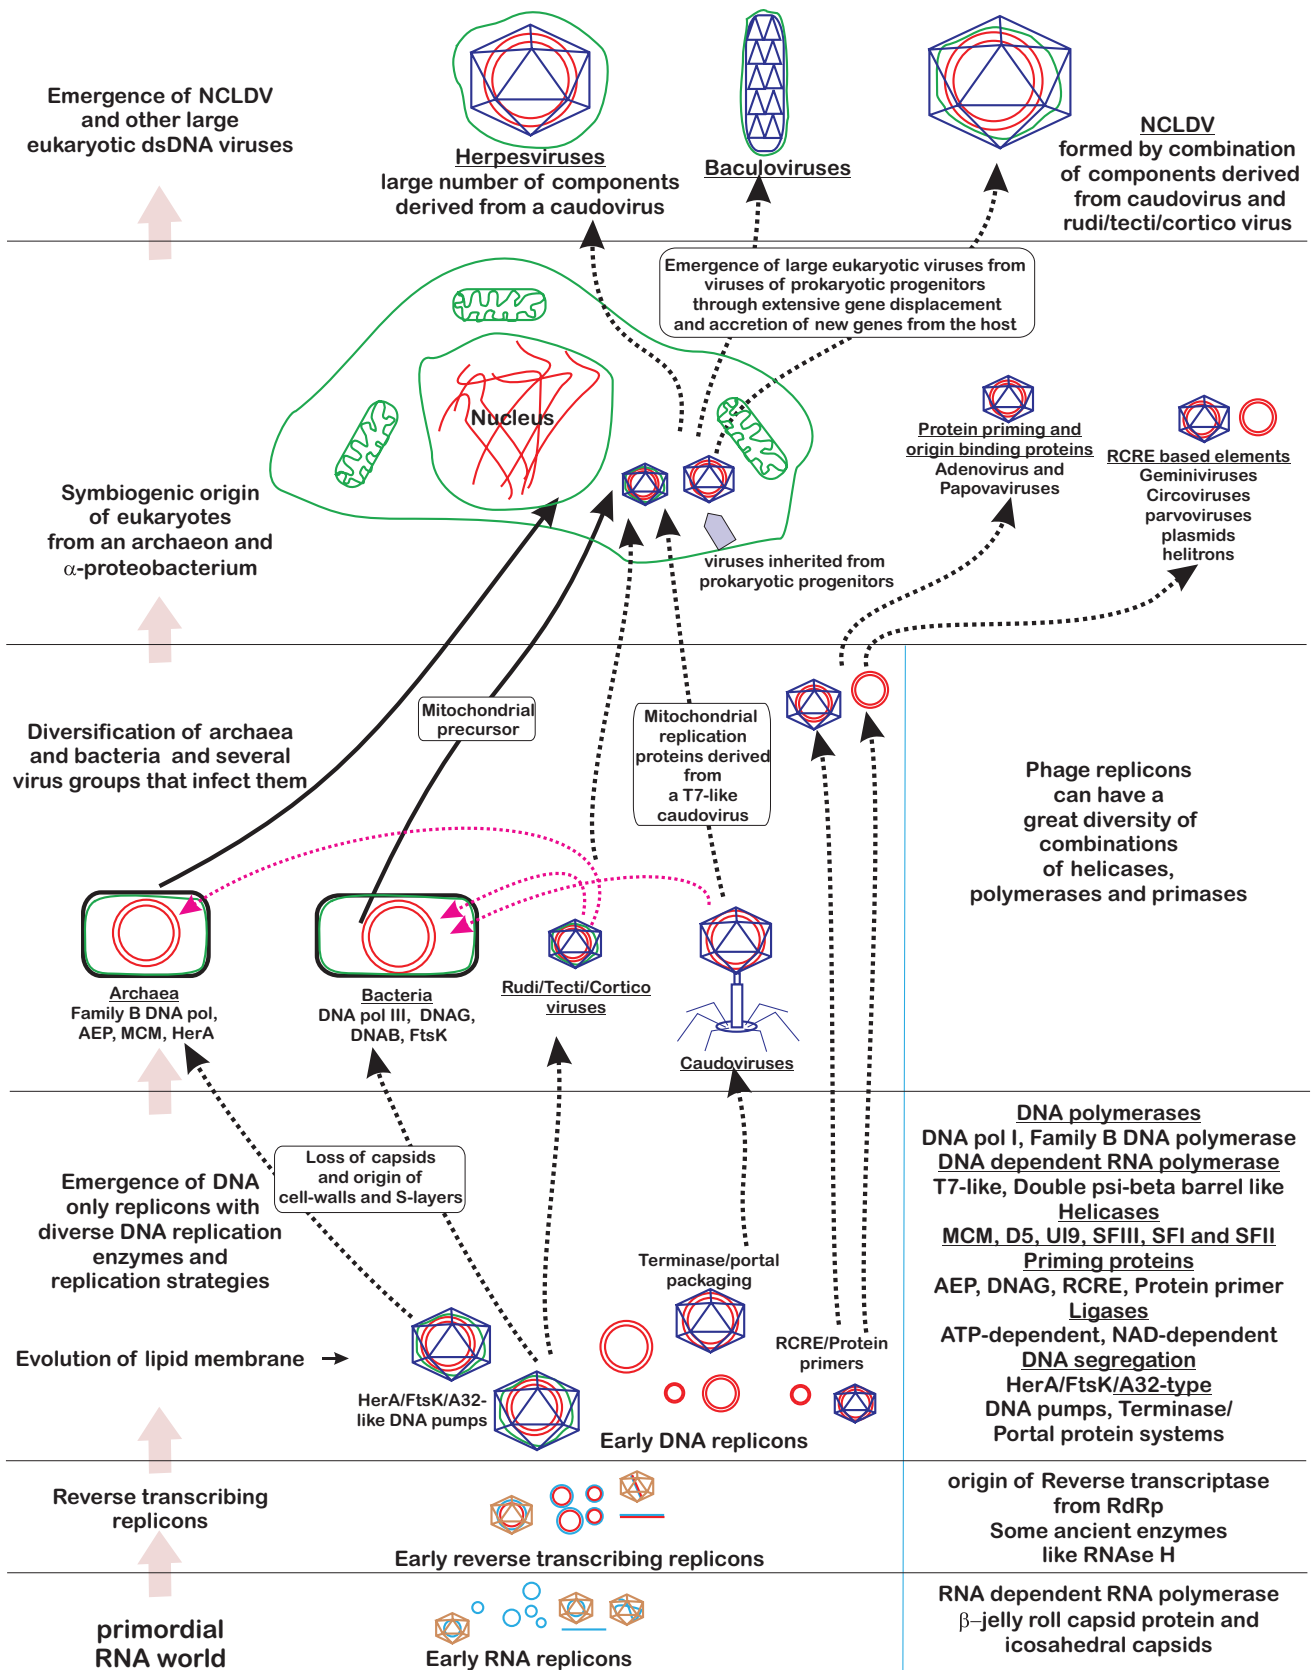

FIGURE 11.2. A plausible scenario for the origin of viruses. Major evolutionary transitions are shown on the **left** of the figure, while the innovations that occurred at each of these transitions are listed on the **right**. Colors are as follows: blue, RNA genomes; red, DNA genomes; green, lipid membranes. (Reprinted from Iyer LM, Balaji S, Koonin EV, et al. Evolutionary genomics of nucleocytoplasmic large DNA viruses. *Virus Res* 2006;117:156–184, with permission from Elsevier. Figure kindly provided by Eugene Koonin.)

so that the times of origin of key human pathogens like variola virus (VARV; the agent of smallpox) are still the source of considerable debate.^{102,135,206}

Virus–host co-divergence has also been used to date the origin of a number of RNA viruses and retroviruses, although these estimates have sometimes proven controversial. Perhaps the most compelling case to date concerns the retrovirus simian foamy virus (SFV), where a statistically significant match between the phylogenetic trees of host and virus may extend to

at least 30 million years^{137,217} (Fig. 11.3), and where the analysis of endogenous foamy viruses places their evolutionary history in mammals to over 100 million years.¹¹⁴

While *bona fide* examples of virus–host co-divergence constitute a powerful way to date the age of specific viruses, it is also the case that co-divergence is sometimes claimed without any associated statistical test, especially when a small number of taxa are involved such that any resemblance between host and virus phylogeny could occur by chance alone. Given that

FIGURE 11.3. Long-term co-divergence between simian foamy virus (SFV) and its primate hosts. The tree on the left comprises 55 primate species and was inferred using mitochondrial COII sequences. The tree on the right contains 44 SFV sequences and was inferred using the viral *pol* gene. Strong host–virus associations are shown as horizontal lines, while incongruent relationships (i.e., host jumps) are shown as crossed lines (note that some hosts have no SFV associated with them). Host–virus co-divergence events are depicted by solid circles at the nodes. The match between the host and virus trees is far stronger than expected by chance ($p = 0.007$). Branch lengths are drawn to scale of nucleotide substitutions per site. (From Switzer WM, Salemi M, Shanmugam V, et al. Ancient co-speciation of simian foamy viruses and primates. *Nature* 2005;434:376–380; reprinted by permission from Macmillan Publishers Ltd.)

cross-species transmission is a very common mode of virus macroevolution, it can be dangerous to construct a time scale of virus evolution without statistically significant co-divergence. In addition, there are a number of other evolutionary processes that can lead to a match between host and virus phylogenies that do not entail co-divergence. For example, it could be that cross-species transmission occurs more often among closely related host species.²¹⁵ This *preferential host switching*³⁶ may produce phylogenetic patterns that are difficult to distinguish from those of co-divergence. A good example is provided by the primate lentiviruses that infect humans (human immunodeficiency virus [HIV]), chimpanzees (simian immunodeficiency virus [SIV] cpz), and gorillas (SIVgor). That these three viruses are very closely related and infect related hosts might at face value be taken to mean that host and virus have co-diverged for several million years. However, closer inspection of the relevant virus phylogenies revealed that the genetic diversity in each case was in fact due to more recent cross-species transmission. Indeed, cross-species transmission involving very closely related host species appears to be common in viruses.¹¹⁹

Using heterochronous samples to calibrate the virus molecular clock is an extremely powerful and increasingly popular way to study the time scale of virus evolution in the recent past and is the most common method used with RNA viruses where measurable sequence evolution is a routine observation. However, it is also an approach where erroneous conclusions can be drawn if not performed with care. Because large numbers of gene sequences where the precise date of sampling is known are now available, and because virus evolution is often relatively clock-like, it is a straightforward exercise to date the age of samples of genetic diversity.⁴⁹ In some cases divergence times estimated in this manner can be very accurate. For example, an analysis of heterochronous samples of human influenza A virus was able to accurately reconstruct the seasonal peaks and troughs in the population size of this virus.¹⁸⁴ However, while these molecular clock approaches can work well for recent virus evolution—that is, for time scales covering that last few hundred years—they are prone to error at far deeper divergence times, providing a picture of virus evolution that is far too recent. An illustrative example of this effect is provided by the case of the SIVs. While molecular clock studies of SIV evolution using heterochronous samples place this on a time scale of hundreds of years, a calibration based on the biogeographic separation of Bioko Island from the coast of West Africa gave dates of at least 32,000, and perhaps over 100,000 years.²³³ More generally, there are cases in the literature where sensible preconception says that a specific virus should be a certain age, usually because it is thought to have diverged with a particular host species or is associated with a particular event in human history, yet molecular clock studies present a far more recent depiction of its origin.⁹¹

More difficult to explain is precisely why recently calibrated molecular clocks fail so badly in the estimation of ancient divergent times. The most likely explanation is that the statistical models used to estimate the number of nucleotide substitutions separating any two sequences fail to adequately account for all the details of virus evolution, thereby greatly underestimating the true numbers of mutations that have accumulated.^{91,94} In short, there has been excessive site saturation that leads to erroneous estimates of divergence times. At present there is no clear way to resolve this problem, although

a likely path for the future is the development of more sophisticated models of nucleotide and amino acid substitution.

The final, and most recently developed, way to infer the time scale of virus evolution involves the use of endogenous viral sequences that are a common component of eukaryotic genomes. Endogenous genomic copies of exogenous viruses that have entered the germline are particularly commonplace in retroviruses, and it is estimated that approximately 5% to 8% of the human genome is composed of endogenous retrovirus, comprising at least 31 distinct families.¹¹⁵ In addition, there is a growing list of endogenous RNA and small DNA viruses, also referred to as endogenous viral elements (EVEs), usually composed of partial virus genome sequences.^{94,113}

The importance of endogenous viruses is that they represent a sort of “fossil record” of past viral infections; once integrated into host genomes they cease to evolve like viruses and instead assume the low rates of nucleotide substitution that characterize their hosts, replicating using high-fidelity host DNA polymerases and likely experiencing fewer replications per unit time (Fig. 11.4). Consequently, if the mutational differences between endogenous viruses are known to occur postintegration, such as those observed between the LTRs of a single endogenous retrovirus, between duplicated EVEs, or when there is clear evidence for co-divergence, then divergence times can be estimated in a relatively straightforward manner using host substitution rates.

Molecular clock dating in this manner suggests that the exogenous ancestors of some human retroviruses may have diversified relatively early on in mammalian evolution.¹¹⁵ Most dramatic are cases of when both exogenous and endogenous copies of the same virus exist, which have generally resulted in a radically different picture of the time scale of viral evolution than using clock estimates based on heterochronous samples. For example, estimates of the age of primate lentiviruses based on the use of heterochronous sequences generally results in time scales of thousands of years at most,²⁰⁵ while the presence of endogenous lentiviruses in lemurs suggests that these viruses have circulated in primates for at least several million years.¹¹⁶ The same is true of endogenous viruses that are not retroviruses. Perhaps the most compelling of these are the avian hepadnaviruses, in which the observation of EVEs integrated at the same genomic positions in bird species that diverged at least 19 million years ago strongly suggests that hepadnaviruses are at least of the same age.⁸⁰ This antiquity sits in stark contrast to studies of hepadnavirus evolution based on the use of heterochronous sequences, in which divergence times are measured on scales of a few thousand years.²⁴⁰ The same phenomenon has been proposed for a variety of other RNA viruses, including bornaviruses and filoviruses,^{14,97,113,218} as well as ssDNA viruses of the families *Circoviridae* and *Parvoviridae*.^{15,111,113,136} In each case, integrated copies of these viruses are observed in diverse host species, for example, comprising both placental and marsupial mammals in the case of the filoviruses, and sometimes showing virus–host co-divergence such that they are clearly millions of years old.¹¹³ However, there are also many cases where the phylogenies of the endogenous viruses and their hosts do not match, which complicates estimates of virus divergence times. As more host genomes are sequenced, it is certain that more endogenous viral elements will be discovered, which will undoubtedly shed new light on the true time scale of virus evolution.

FIGURE 11.4. How endogenous virus elements (EVEs) are generated and can be used to estimate the age of viral families.

Examples of different types of mammalian RNA and DNA viruses are shown. Critically, the presence of EVEs in related host species A and B and integrated into the same genomic position indicates that this integration event occurred prior to the divergence of these two species, such that its minimum age can be estimated if it is known when the host species diverged. (From Katourakis A, Gifford RJ. Endogenous viral elements in animal genomes. *PLoS Genet* 2010;6:e1001191. Original figure kindly provided by Rob Gifford.)

Virus Classification

Finally, and as a brief digression, it is useful to discuss the schemes used for virus classification, ranging from orders to species and genotypes, and what they mean in an evolutionary context, particularly as they indirectly relate to the issue of virus origins. The main points to make here are that although a useful and important aspect of comparative biology, all such classification schemes have a large arbitrary component to them, are not based on a specific evolutionary pattern or process, and do not necessarily mean that the viruses in question exhibit a specific set of biological differences. Indeed, these limitations are likely to apply to most microorganisms. To some extent, this arbitrariness sits in contrast to what is seen in sexually reproducing eukaryotes, where *species* represents a distinct and clearly definable evolutionary group—a population of interbreeding individuals. Hence, although what are termed virus *species* may possess phenotypic characteristics that can be defined for each group and form well-supported clusters on phylogenetic trees, this should not be taken as evidence that they have been formed by a distinct evolutionary process that is analogous to reproductive isolation in eukaryotes. The same is also true of the higher-order classifications proposed for viruses (e.g., supergroups, orders, genera) and for those below the level of species (e.g., genotypes or subtypes). All these groupings can be thought of as points in phylogenetic space rather than describing taxonomic groups that have attained a specific level of phenotypic divergence. In other cases viruses are classified simply through estimates of pairwise genetic diversity, with

different levels of diversity signifying the division into species, genotypes, and so forth. Although simple, classification schemes constructed in this manner similarly have no basis in evolutionary theory and may be biased if different lineages evolve at different rates. In sum, it is overly simplistic to think that nature will generate clear-cut divisions in phenotypic and genotypic space that can be used to construct meaningful classification schemes, and hence that systematics tells us anything about virus origins and evolution.

PROCESSES OF VIRUS EVOLUTION

Irrespective of debates over whether viruses are alive, it is clear that they are subject to the same forces that shape the evolution of cellular species, that is, mutation, natural selection, genetic drift, recombination (and reassortment), and migration. I will discuss the first four of these processes in this chapter. Migration, in the guise of viral epidemiology, is discussed elsewhere in this volume.

Mutation and Nucleotide Substitution in Viruses

The simplest way to examine the role of mutation in virus evolution is to measure the rate of its occurrence. Indeed, understanding the factors that shape the speed at which genetic variation is generated in viruses is central to understanding many aspects of their evolution. For RNA viruses mutation can in some ways be thought of as their defining evolutionary

feature, as it occurs at a pace that greatly exceeds that observed in other organisms.

Although mutation is the ultimate source of genetic variation, the pace of evolutionary change can in fact be measured in two rather different ways. One method is to estimate, experimentally, the rate at which mutations are generated *de novo*. Such rates have usually been presented as the number of mutations per nucleotide, per replication or the number of mutations per genome, per replication. However, because of the inherent complexities and biases in making these estimates, it has been suggested that estimates of mutation rate per nucleotide, per cell infection may be more informative.¹⁹⁶ For example, one important complicating factor is that some viruses employ so-called stamping machine replication, in which a single virus acts as the template for all progeny genomes, so that mutations accumulate linearly, while others utilize “geometric” replication, in which some of the early progeny genomes are used as templates to produce further progeny, in turn increasing the rate of mutation accumulation.⁵²

The power of mutation rate estimates is that they reveal the intrinsic error dynamics of the RNA or DNA polymerases used in viral replication and in theory allow a count of each type of mutation—advantageous, neutral, or deleterious—before they have been shaped by natural selection, although it is always difficult to accurately count the number of lethal mutations that are rapidly removed by purifying selection. A detailed compilation of mutation rate estimates for 23 viruses, and accounting for many of the complexities inherent in analyses of this kind, revealed that these rates varied from 10^{-6} to 10^{-4} mutations/nucleotide/cell infection for RNA viruses to 10^{-8} to 10^{-6} mutations/nucleotide/cell infection for DNA viruses¹⁹⁶ (Fig. 11.5). For RNA viruses that replicate with RdRp, an enzyme that lacks a proofreading or repair function, this equates to mutation rates that are usually a little below approximately one per genome, per replication.^{47,48,52} Similarly, the lower mutation rates observed in large DNA viruses clearly

FIGURE 11.5. Comparative rates of mutation in different types of virus and their relationship to genome size. Comparable values from bacteria are also shown. Mutation rates (y-axis) are given per nucleotide per cell infection (s/n/c). See reference 196 for more details including the taxa analyzed. (From Sanjuán R, Nebot MR, Chirico N, et al. Viral mutation rates. *J Virol* 2010;84:9733–9748. Figure kindly provided by Rafa Sanjuán.)

FIGURE 11.6. Relationship between mutation rate and genome size in diverse organisms including RNA and DNA viruses and viroids. The competing evolutionary forces that might be responsible for the limited range of observed error rates and genome sizes are shown. For details see reference 93. Data from reference 75. (From Holmes EC. What does virus evolution tell us about virus origins? *J Virol* 2011;85:5247–5251.)

reflect the higher fidelity of the DNA polymerases employed in their replication cycle. Of particular note is that mutation rate estimates in ssDNA viruses (a maximum of 1.1×10^{-6} , although only two estimates are available) are higher than those of large dsDNA viruses (which range from 5.9×10^{-8} to 5.4×10^{-7}), even though ssDNA viruses have such small genomes that they use host DNA polymerases for replication. It is therefore possible that the relatively high mutation rates in ssDNA viruses reflect less efficient proofreading and excision repair on ssDNA and/or frequent deamination.⁵¹ The study of Sanjuán et al.¹⁹⁶ was also of note in that it revealed that retroviruses such as HIV have error rates that overlapped with those of RdRp-utilizing viruses, even though earlier studies suggested that RT exhibits higher fidelity than RdRp.^{47,48,143}

From a broader perspective these estimates of mutation rate are compatible with the idea that for all living systems there is a strongly inverse relationship between mutation rate and genome size (Fig. 11.6).^{75,93} It also seems likely that the systematic difference in mutation rate and genome size between RNA and DNA viruses is associated with many of the main evolutionary distinctions between these two types of infectious agents that are discussed throughout this chapter, such that they can be thought of as occupying very different regions of evolutionary parameter space (Table 11.1).

Although they utilize related DNA polymerases, mutation rates in large DNA viruses are higher than those of bacteria and eukaryotes, which may reflect an absence of the full set of repair enzymes and pathways in the former. However, there are two possible exceptions to this rule. First, there is currently no estimate of mutation rates in mimivirus or megavirus, although these are expected to fall within the bacterial range (as the genome sizes of these viruses overlap with those of bacteria), and hence are lower than that observed in any virus to date.

TABLE 11.1 The Differing Evolutionary Parameter Spaces Occupied by RNA and DNA Viruses^a

Characteristic	RNA (and ssDNA) viruses	dsDNA viruses
Mutation rate (per nt)	High	Low
Genome size	Small (<32,000 nt)	Can be large (>100,000 nt)
Population sizes	Usually large	Can be small
Recombination	Often low rates	Often high rates
Epistasis	Antagonistic	Synergistic ^b
Gene duplication	Apparently rare	Common
Lateral gene transfer	Apparently rare	Common
Overlapping reading frames	Common	Relatively rare

dsDNA, double-stranded DNA; ssDNA, single-stranded DNA.

^aNote that the properties shown are “average” ones, and cannot be applied to every taxon in each category (particularly for DNA-based organisms).

^bBy inference only: the extent and sign of epistasis has not been measured in dsDNA viruses.

Second, we similarly lack an estimate of mutation rate in the small dsDNA viruses, such as the papillomaviruses. Although the relationship depicted in Figures 11.5 and 11.6 implies that these viruses will mutate rapidly, most estimates of substitution rate in papillomaviruses are in a similar range to those of large DNA viruses.^{68,187} This implies that papillomaviruses similarly mutate relatively slowly, which would break the simple relationship between mutation rate and genome size.

The relationship between mutation rate and genome size is of twofold importance. First, because it incorporates genetic systems ranging from viroids to eukaryotes, it covers at least eight orders of magnitude of both genome size and mutation rate, and few things in biology encompass such diversity. Second, it implies that mutation rates that are either too high or too low are selected against.⁹³ With respect to the latter, a popular idea is that viral mutation rates (and particularly the high mutation rates of RNA viruses) are the result of an evolutionary trade-off, either between replication rate and replication fidelity⁷⁴ or between the rates of deleterious and advantageous mutation.^{52,213} Data can be cited in support of both relationships.^{92,144,224} The possible trade-off between the rates of deleterious and advantageous mutation seems particularly compelling. On the one hand, as viruses will be commonly exposed to changing environments (i.e., different hosts, a variety of cell types, frequent immune pressure), the generation of some genetic variation via mutation is likely to be selectively advantageous. This idea also has experimental support; RNA polymerases with lower fidelity are sometimes selectively favored over those with higher fidelity.^{92,144,224} On the other hand, there must be an upper limit on the mutation rates experienced by viruses (and all living systems), as excessive error will result in major fitness losses. Powerful evidence for this ceiling on mutation rates is provided by experiments invoking *lethal mutagenesis* (see later), in which artificially increasing error rates with mutagens such as 5-fluorouracil and ribavirin result in an excessive mutational load.^{26,171} It is therefore likely that RNA viruses exist close to their maximum tolerable mutation rates, which in turn imposes an upper limit on genome size. However, it is also likely that RNA viruses are mechanistically unable to reduce their error rates to the levels associated with DNA polymerases. A higher-fidelity RNA polymerase would

need to be more complex, and hence longer, than those that currently exist, yet this cannot evolve because, by increasing genome length, it will result in too many deleterious mutations. This evolutionary conundrum is commonly referred to as *Eigen's paradox* and is a key element in theories for the early evolution of genomic complexity.

The second measure of the pace of virus evolution is the rate of nucleotide substitution per nucleotide site, per year (subs/site/year). As this measure reflects the population success of any mutation, it by necessity incorporates the action of natural selection. Accordingly, deleterious mutations that have been removed by purifying selection will not be counted, while advantageous mutations will be fixed more rapidly than neutral ones. Nucleotide substitution rates are usually far easier to estimate than mutation rates and as such provide a simple and powerful means to compare patterns of virus evolution.

As with rates of mutation, rates of nucleotide substitution vary markedly among viruses. Across RNA and DNA viruses as a whole, nucleotide substitution rates vary by over five orders of magnitude, in large part reflecting the differences in background mutation rate described earlier. Hence, most substitution rates in RNA viruses fall within an order of magnitude of a value of 1×10^{-3} subs/site/year,^{87,110} while the rates in many dsDNA viruses are closer to 1×10^{-8} subs/site/year.^{89,145,148,187} Undoubtedly, our understanding of viral substitution rates would be improved by measures of evolutionary dynamics in the smallest (i.e., viroids) and largest (i.e., mimivirus) viral systems.

Most of the variance in the substitution rates in both RNA and DNA viruses likely reflects virus-specific differences in either mutation rate, replication rate, or both. Mutation rates have been discussed earlier, and some studies have revealed that substitution rates in RNA viruses are negatively associated with genome size as expected if background mutation is the main determinant of substitution rate.¹¹⁰ Although few direct estimates of replication rate are available, they likewise clearly play a major role in shaping substitution rates. For example, although the retrovirus SFV likely has an RT-associated error rate that is similar to those of other retroviruses, its co-divergence with primates for over 30 million years (Fig. 11.3) leads to estimates of the substitution rate of only 1.7×10^{-8} subs/site/year.²¹⁷ This most likely reflects a low rate of replication,

although this merits further investigation. Similarly, replication rates appear to be low in papillomaviruses, in which virus replication occurs simultaneously with the division of host epithelial cells, at approximately 10 to 100 generations per year,¹⁹ which likely contributes to the low substitution rates estimated in this virus. In contrast, that DNA viruses often replicate more rapidly than their hosts may in part explain why virus substitution rates are higher than host substitution rates even though they utilize similar polymerases. For example, the Bo17 protein of bovine herpesvirus 4 represents a viral capture of the mammalian 2 β -1,6-N-acetylglucosaminyltransferase-mucin protein.¹⁴⁵ As a phylogenetic analysis revealed that this gene was captured from the host after the split between cattle and African buffalo approximately 1.5 million years ago, it was possible to estimate that the viral gene had evolved 20 to 30 times faster than its cellular homolog.¹⁴⁵ Finally, for persistently infecting viruses, substitution rates may also differ between periods of intra- and interhost evolution. For example, HIV-1 substitution rates are higher within than among hosts.¹⁴² This may be because intra-host HIV evolution is dominated by the positive selection of immune escape mutations or because some of the mutations that occur within hosts are purged at interhost transmission, thereby reducing the substitution rate.

Although most estimates of substitution rate suggest a fundamental division in virus evolution in which RNA viruses evolve rapidly and DNA viruses evolve slowly, there are a number of important exceptions. First, a number of RNA viruses are reported to evolve anomalously slowly.^{99,216} A much debated example is the rodent hantaviruses (*Bunyaviridae*), which are often claimed to have co-diverged with their murid hosts over many millions of years, which would lead to rates of nucleotide substitution in the range of 10^{-7} subs/site/year.¹⁷⁸ Clearly, these substitution rates are far closer to those of dsDNA viruses than to other RNA viruses. However, there are also important mismatches between the virus and host phylogenies, most notably that hantavirus sequences from various insectivores are mixed with those sampled from rodents,⁶ and hantavirus substitution rates estimated over the short term fall within the usual RNA virus range.¹⁸⁵ As a consequence, the true rate of nucleotide substitution in the rodent hantaviruses is uncertain. Second, ssDNA viruses exhibit substitution rates—often in the realm of 10^{-4} subs/site/year—that are closer to those of RNA viruses than to large DNA viruses. Such high rates have now been described in both carnivore²⁰³ and human^{167,201} parvoviruses, in porcine circovirus,⁶⁷ and in plant geminiviruses.^{51,222} Although the mutation rates of ssDNA viruses are higher than those of large DNA viruses, they do not fully explain the elevated substitution rates.¹⁹⁶ It is therefore possible that rapid nucleotide substitution in ssDNA viruses reflects short generation times and/or strong positive selection, the latter of which is well documented in the carnivore parvoviruses following cross-species transmission.^{172,203} An important caveat is that both endogenous circoviruses and parvoviruses have now been documented, which suggests that these viruses are ancient.^{111,113} Unfortunately, however, the sequences of these endogenous viruses are often so divergent as to challenge any attempt to reliably estimate rates of evolutionary change.

Finally, there are also cases in which large DNA viruses evolve more rapidly than might be expected. A case in point is VARV, in which estimates of the substitution rate fall between 10^{-6} and 10^{-5} subs/site/year, and hence are far higher than those

observed in other large DNA viruses where evolutionary rates have been inferred, particularly the herpesviruses.^{68,102,206} In addition, VARV exhibits a strongly linear relationship between genetic distance and time of sampling (i.e., measurable evolution) that is also indicative of a high substitution rate.⁶⁸ It is therefore possible that VARV has been subject to strong positive selection (at least in the recent past) and that this has elevated the substitution rate to above that expected by neutral mutation pressure alone. Such strong positive selection may be a characteristic common to the orthopoxviruses.¹⁵¹

Natural Selection and Genetic Drift in Virus Evolution

Despite long-standing debates over whether natural selection or genetic drift is the more important process of evolutionary change at the molecular level, there is little doubt that viruses provide some of the very best examples of natural selection in action. The literature contains numerous examples of natural selection for such properties as immune evasion (of antibody, T-cell, or innate responses), antiviral resistance, and the adaptation to new cell types and host species. The strength of these selection pressures is readily apparent in the fact that the genomes of large DNA viruses such as poxviruses and herpesviruses contain many genes dedicated to immune evasion. As there are numerous examples of each of these types of positive (i.e., Darwinian) selection for both RNA and DNA viruses, and they are generally not contentious, I will not discuss them here. A more pressing question is, what proportion of all the mutations that arise and are fixed in viral genomes are entirely free of natural selection and hence evolve in a strictly neutral manner, compared to the proportion that are fixed because they are selectively advantageous? Simple population genetic theory predicts that natural selection should be a potent force in viral evolution. Natural selection dominates molecular evolution when the product $N_e s \gg 1$, where N_e is the effective population size, and s the selection coefficient (i.e., the fitness of the mutation in question). Although easy to state, estimating these parameters is usually thwarted with difficulties, such that the measures obtained are often only approximate. As a consequence, conclusively determining the role of natural selection versus genetic drift in viral evolution is inherently difficult, although a number of important generalities can be made.

In the case of RNA viruses, it is likely that few amino acid mutations are strictly neutral (i.e., $s = 0$), with most clearly deleterious. In particular, their small genomes ensure there is extensive pleiotropy, epistasis, and multifunctionality such that there is little evolutionary elbow room. Indeed, mutagenesis studies of vesicular stomatitis virus (VSV) revealed that nearly 40% of random mutations are lethal, another 29% deleterious, a further 27% neutral, and only 4% beneficial,¹⁹⁵ although these estimates only relate to fitness effects in a single cell and a far larger proportion of mutations are expected to be deleterious (or lethal) when considering the entirety of the virus life cycle. In addition, as recombination is infrequent in many RNA viruses (see later), there will be strong linkage between neutral mutations and those that are either fixed or purged by natural selection, such that their evolutionary fates will be linked. The same is also likely to be true of ssDNA viruses, which are also characterized by very small genome sizes. Accordingly, most estimates of the ratio of nonsynonymous (d_N) to synonymous (d_S) nucleotide substitutions per site (ratio

d_N/d_S , a common measure of selection pressures, with $d_N/d_S = 1$ indicative of selective neutrality) in RNA and ssDNA viruses suggest that purifying selection is the most common evolutionary force (i.e., $d_N/d_S < 1$).^{92,101} However, the case of large DNA viruses is far less clear, in large part because relatively few studies of their molecular evolution have been undertaken. One comparative study of d_N/d_S revealed weaker purifying selection in DNA than RNA viruses,¹⁰¹ suggesting that the former may possess a class of neutrally evolving amino acid sites. Although the explanation for this effect is unclear, it may be a function of the large genome sizes in large dsDNA viruses, which allow more genetic redundancy through the presence of duplicated genes (see later). Alternatively, it may be indicative of greater levels of positive selection in DNA viruses, as also suggested by the high rates of nucleotide substitution documented in some.⁶⁸ Determining the exact nature of the selection pressures acting on large DNA viruses, including the fitness of individual mutations, is clearly an area where a combination of experimental study and evolutionary analysis will be of fundamental importance.

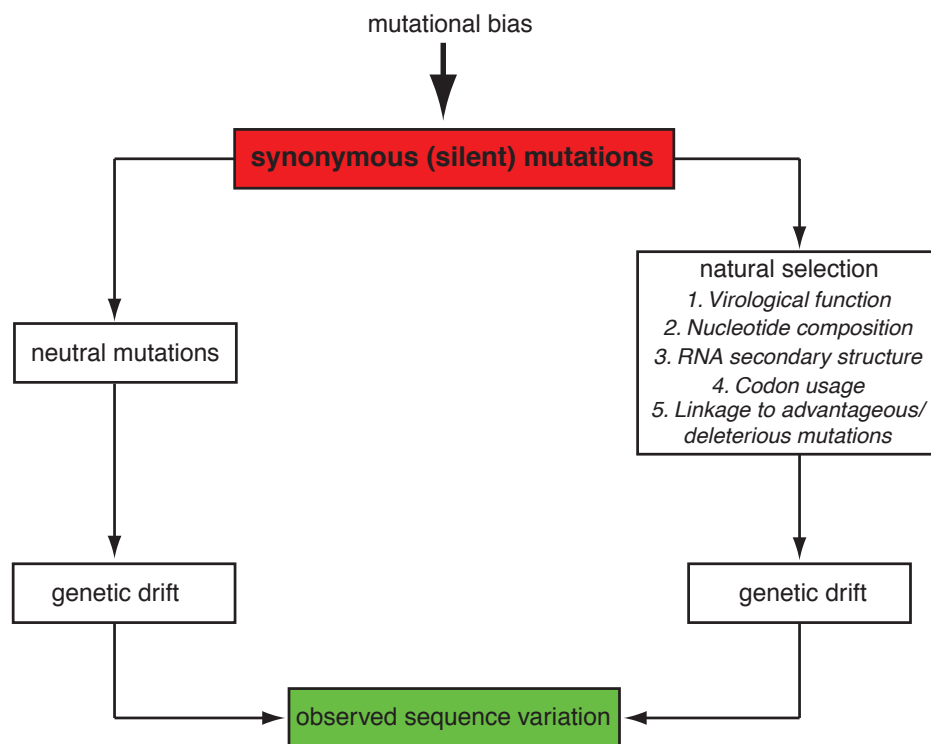

Obviously, the most likely class of neutral sites in viral genomes is those that do not code for protein. For RNA viruses it is debatable how many nucleotide sites fall into this category, particularly as these viruses contain very few, if any, clear-cut examples of “functionless” noncoding RNA, such as pseudogenes and introns. A similar story can be told for small DNA viruses, either single or double stranded, which can be considered as exemplars of genomic efficiency. Indeed, many small DNA viruses, such as circoviruses, parvoviruses, and hepadnaviruses, contain extensive overlapping reading frames, suggesting that they are under strong selective pressure to maximize the phenotypic diversity they can produce from a restricted genomic space. Importantly, the existence of overlapping reading frames changes the selective regime acting on many

nucleotide sites. In particular, synonymous sites in one reading frame are likely to be nonsynonymous in another, such that they must be subject to some sort of purifying selection. Similarly, although some pseudogenes are present in the genomes of large DNA viruses,⁷⁶ there are relatively few gene overlaps, and it is unclear whether they contain stretches of purely nonfunctional DNA. For example, although the genomes of herpesviruses and poxviruses contain many regions that do not code for protein (~5% to 15% of the genome in the case of poxviruses), these may still encode promoters, transcription termination signals, functional RNA molecules, or other functional elements. One candidate for truly nonfunctional sequences is the imperfect tandem repeat seen in the intergenic regions of some poxviruses and that exhibit various deletions and duplications. Understanding the potential functions, if any, of these noncoding regions is an important goal for the future.

Evolution of Synonymous Sites

Perhaps the most intense debates on the nature of selection pressures acting on viral genomes concern synonymous (silent) nucleotide sites. In eukaryotes, and particularly mammals, there is good evidence that many synonymous nucleotides are subject to only weak (if any) selection pressures and therefore evolve in an effectively neutral manner, although selection on silent sites is being increasingly documented³¹ and can take a variety of forms (Fig. 11.7). Under neutral evolution the nucleotide composition of synonymous sites tends to match that of the genome region in which they are located, reflecting the action of background mutation pressure. That in all viruses genome-scale levels of synonymous variation are far higher than those observed at nonsynonymous sites indicates that the fitness effects of synonymous mutations are usually less than those of nonsynonymous mutations (as is true of all living systems). However, this does not necessarily mean that

FIGURE 11.7. Evolutionary processes acting on synonymous (silent) nucleotide sites in viruses. The first bias is generated by the basic process of mutation, which may make some types of mutation (e.g., specific nucleotide transitions) more frequent than others. Those synonymous mutations that do arise may either be neutral, so that they are not subject to natural selection, or exhibit fitness differences (listed), in which case they are put through the sieve of natural selection. Both neutral and advantageous mutations are also subject to random genetic drift.

FIGURE 11.8. The relationship between recombination rate, sequence similarity, and RNA secondary structure in the *env* (envelope) gene of human immunodeficiency virus type 1 (HIV-1). Recombination rates are shown in light blue, conserved RNA structures in dark blue, and sequence similarity (identity) in brown. The location of recombination hotspots are marked by light blue bars at the bottom of the figure. (Adapted from Simon-Loriere E, Martin DP, Weeks KM, et al. RNA structures facilitate recombination-mediated gene swapping in HIV-1. *J Virol* 2010;84:12675–12682, which should be consulted for more details. Figure kindly provided by Etienne Simon-Loriere.)

synonymous mutations are strictly neutral, particularly at large effective population sizes where natural selection is especially potent. In fact, there is mounting experimental evidence that synonymous mutations can sometimes have a major effect on viral fitness, as they contain the signals for such processes as promotion, transcription, and encapsidation,^{147,168} which means that all studies of d_N/d_S should be interpreted with care.

The most discussed ways in which natural selection might act on synonymous sites are through RNA secondary structures and codon usage. RNA secondary structures are a common feature of many RNA viruses, can occur in both untranslated regions and coding regions, and can comprise genome-scale interactions.^{210,226} It is well established that these RNA secondary structures can have a major impact on key elements of virus function, such as containing important signals for such processes as replication and translation. RNA secondary structures may impact on other aspects of virus evolution including shaping, to some extent, genome-wide recombination frequencies²¹² (Fig. 11.8). Similarly, functional RNA structures have been noted in a number of DNA viruses.¹⁵⁶ Evidently, the presence of RNA secondary structures strongly argues against the selective neutrality of many synonymous sites,²⁰⁹ although their precise effects on fitness have rarely been documented.

The second form of natural selection that may act on synonymous sites is codon usage. As with RNA secondary structure, changing codon usage may have a profound effect on fitness. As a dramatic case in point, experimental alteration of synonymous codon usage resulted in the attenuation of poliovirus.³⁹ When genetic drift dominates molecular evolution, synonymous codon usage is set by the background (i.e., neutral) mutational bias in the organism in question. In

contrast, natural selection could shape codon choice by optimizing the match between codon and anticodon so as to increase the accuracy and/or efficiency of protein translation (although a variety of other selective explanations exist¹⁷⁷). While viruses often exhibit strong biases in codon usage, the explanations for these biases have usually not been resolved. Many RNA viruses utilize synonymous codons that tend to match the nucleotide composition of the viral genome as a whole, suggesting that selection on codon choice is likely to be relatively weak and mainly set by background mutational pressure¹⁰⁸ or that selection is acting on the overall nucleotide composition (see later). However, direct selection for a specific pattern of codon usage seems to characterize other viruses. For example, codon usage bias in Epstein-Barr virus is associated with levels of viral gene expression, varying between the latent and productive phases,¹¹² while there is a strong match between codon usage and host transfer RNA (tRNA) availability in papillomavirus, which determines the levels of capsid protein expression.²³⁹ Similarly, a study of honeybee viruses revealed the same pattern of codon usage in unrelated RNA viruses, indicative of a bee-specific selection pressure.³³ More interesting is the case of hepatitis A virus in which codon usage seems to be set by the kinetics (rather than the accuracy) of protein translation such that rare codons that utilize nonabundant tRNAs are used, which slows down the translation process to ensure proper protein folding.⁵

As noted earlier, it is also possible that overall nucleotide composition is the selectively determined trait, which has a secondary effect on codon usage bias. Evidence for such a process is the major host-specific differences in nucleotide composition observed in some viruses.^{10,109} For example, nucleotide

composition noticeably changes in influenza A virus following host jumps from birds to mammals, although precisely why is unclear.⁸⁵ Systematic differences in nucleotide composition also characterize DNA viruses, and nucleotide compositions can vary enormously even at the intrafamily level.¹⁴⁹ For example, CpG nucleotide frequency was observed to be the major correlate of codon usage bias in vertebrate DNA viruses, again pointing to the importance of genome-wide mutation pressure.²⁰² However, small DNA viruses were observed to have CpG contents far below that expected given their overall nucleotide composition, in contrast to the situation in large DNA viruses, although the explanations for this difference are unclear.²⁰²

Effective Population Size and Population Bottlenecks

After the selective coefficient of mutations, the second factor that determines the respective roles of natural selection and genetic drift in virus evolution is the effective population size (N_e), which is usually far lower than the census population size, N . Available data indicate that N_e fluctuates dramatically during the life cycle of most viruses. For all exogenous viruses, large values of N_e are most likely observed within an individual host following multiple rounds of replication and at the epidemiologic scale. Natural selection is expected to be an efficient force in these cases. For example, perhaps 10^{10} virions are produced by HIV-1 replication per day in every infected individual,¹⁷⁵ with some 10^7 human hosts HIV-infected on a global scale. In addition, the burst sizes of many acute viruses will be large, such that within-host values of N_e are expected to be high for at least some parts of the virus life cycle. The exception to this rule may be latent viruses, in which effective population sizes are often likely to be relatively small, reflecting a lack of active replication.

Conversely, low values of N_e , reflecting the time when genetic drift is strongest and perhaps overriding the action of natural selection, will generally occur at interhost transmission. At this point in the virus life cycle a major population bottleneck may be a common occurrence, although this is also likely to be at least in part determined by the mode of transmission and hence the infecting dose; for example, vertical transmission (wide bottleneck) might be expected to be associated with the transfer of more viruses between hosts than sexual transmission (narrow bottleneck).¹³⁴ In some cases, including HIV-1, it is possible that the transmission bottleneck is so extensive that new infections are initiated by a single virus particle,⁶⁹ which would obviously result in a major stochastic effect on virus genetic diversity. Similarly, experimental studies of plant viruses have commonly revealed the existence of extensive population bottlenecks, both at interhost transmission and as the virus moves through an individual plant^{3,191} and which may also be true of vector-borne viruses of animals.²¹⁴ In these cases the stochastic effects of genetic drift are expected to be strong, even to the extent of allowing many slightly deleterious mutations to rise to appreciable frequencies, although to date there have been few *in vivo* experiments to address this issue. Interestingly, some comparative sequencing studies have suggested that interhost transmission might be associated with relatively wide population bottlenecks. For example, multiple viral lineages passed among horses during experimental transmissions with equine influenza virus,¹⁶² while the occurrence of

mixed infections in viruses such as influenza^{78,162} and dengue¹ also suggests that transmission bottlenecks might be relatively broad. Overall, it is evident that a great deal more work is needed to fully understand the nature and scale of population bottlenecks in viruses and what this means for the relative frequencies of natural selection versus genetic drift, particularly in natural as opposed to experimental infections.

Evolutionary Interactions: Epistasis, Defecting Interfering Particles, and Complementation

A common assumption in many evolutionary studies is that nucleotide sites evolve independently. However, this assumption is often highly simplistic as epistatic interactions among mutations are a regular occurrence in viral genomes. Not only might such epistasis be of great functional importance, such as that resulting from RNA or protein secondary structure, but it may also tell us a great deal about the basic mechanics of virus evolution.

Epistatic effects can be antagonistic (positive), in which case they reduce the effect of combined mutations on fitness, or synergistic (negative), in which case they increase this effect. Although determining the nature of epistasis represents a major technical challenge because it entails a precise measurement of the combined fitness effects of multiple mutations, there is growing evidence for epistasis in viruses, and particularly in RNA viruses where experimental studies are rather easier to perform. Importantly, most of the epistatic interactions determined to date in RNA viruses are antagonistic rather than synergistic,^{20,125,197} which has major implications for understanding why recombination evolved in viruses (see later). Similar epistatic effects have been observed in small ssDNA viruses.¹⁷⁴

It is useful to discuss the extent of epistasis in the context of mutational robustness, which is a way in which phenotypes can be “protected” against the adverse effects of deleterious mutation pressure. Robustness can be generated in a number of ways, including through genetic redundancies such as duplicated genes, through the creation of neutral spaces as might be contained in RNA or protein secondary structure, or by complementation.^{45,157} There is a strong relationship between the level of genetic redundancy and epistasis, such that antagonistic epistasis is most common in genomes that are characterized by little redundancy and weak robustness, as is the case for RNA and ssDNA viruses (Fig. 11.9).^{58,194} Hence, when mutations occur in viruses with small genomes, which contain many overlapping reading frames and functions, they will tend to repeatedly damage the same functions, leading to antagonistic epistasis.²²⁹ Conversely, synergistic epistasis is more commonplace in larger DNA-based organisms that exhibit a greater level of genetic redundancy and robustness, of which duplicated genes are a good example, which allows them to tolerate a certain number of deleterious mutations (Fig. 11.9). Where large DNA viruses fall on this spectrum is uncertain, as there have been no experimental measures of the rate and sign of epistasis in these organisms to date. However, that multigene families are a common occurrence in large DNA viruses, resulting in a level of genetic redundancy, suggests that most of the epistatic interactions that occur in these viruses will be synergistic.

While individual mutations in viruses can interact through epistasis, whole virus genomes can interact through the presence of defective interfering (DI) particles and complementation.

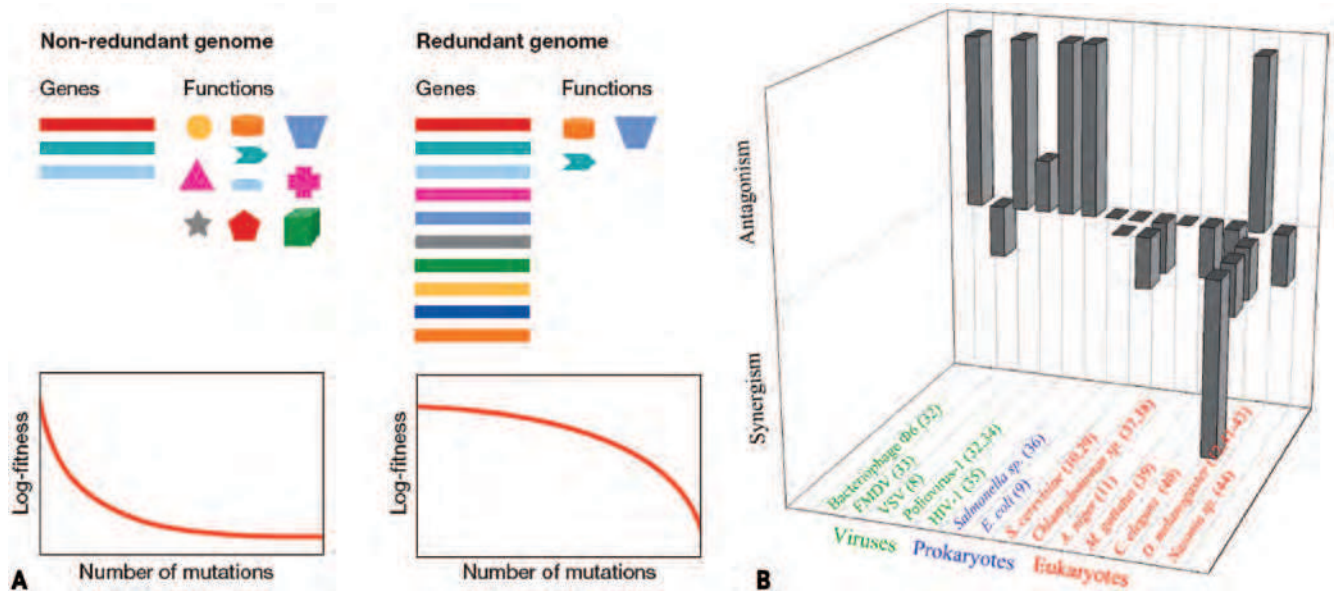

FIGURE 11.9. Redundancy and epistasis in viruses. **A:** Differing properties of robust (redundant) and nonrobust (nonredundant) genetic systems. In robust genetic systems that contain many genes, which may include large DNA viruses, the presence of genetic redundancy means that individual mutations have weak fitness effects and interact through synergistic epistasis. In contrast, in nonrobust systems such as RNA viruses and single-stranded DNA (ssDNA) viruses, there are few genes, and hence little genetic redundancy, so that single genes have multiple functions and single mutations have strong fitness effects. This results in antagonistic epistasis. (From Elena SF, Carrasco P, Daròs JA, et al. Mechanisms of genetic robustness in RNA viruses. *EMBO Rep* 2006;7:168–173.)

B: The type of epistasis seen in a variety of organisms: long bars, significant epistasis; short bars, nonsignificant epistasis; flat bars, no evidence for epistasis. For details see reference 92. (From Sanjuán R, Elena SF. Epistasis correlates to genomic complexity. *Proc Natl Acad Sci U S A* 2006;103:14402–14405; copyright 2006 National Academy of Sciences, U.S.A.)

DI particles are a common observation in many virus families⁹⁸ and have been implicated in a number of virological traits, including persistence.¹⁹⁰ DI particles often harbor large genomic deletions and compete with fully functional viruses during replication because they are able to replicate faster. DI particles have a number of interesting evolutionary consequences, although these will usually be short term. First, the high frequency of DI particles further illustrates the high rate at which deleterious mutations are produced in virus populations, including large-scale deletions. Second, as noted later, the polymerase error process that generates DI particles also has important implications for the evolution of recombination in viruses. Third, because they are able to replicate more rapidly than full-length viral genomes, DI particles may theoretically inhibit the spread of the advantageous mutations that are present on full-length viral genomes, if only transiently.

DI particles are likely to be maintained in virus populations through complementation, which is predicted to be a common occurrence at high multiplicity of infection, and which has been relatively frequently documented in both RNA (e.g., references 77, 221) and DNA viruses (e.g., references 37, 150). Perhaps the most interesting evolutionary consequence of complementation is that it allows deleterious mutations to persist for extended periods.⁷³ Until relatively recently, complementation was a process that had only been observed *in vitro*, such that DI particles were thought to survive just a few generations and therefore had little long-term evolutionary consequence. However, more recent analyses reveal that

complementation may be frequent in nature⁷² and may extend over very long time periods.¹ As a consequence, complementation may play more of a role in virus evolution than is usually envisioned, particularly in the context of how deleterious and advantageous mutations interact with each other, although this will evidently require further study.

The Evolution of Viral Recombination

A combination of comparative genomics and experimental study has provided growing evidence for the action of recombination, and its sister process reassortment, in viral genomes, although rates of virus recombination are often far lower than those documented in many cellular species. At the sequence level recombination is commonly apparent as incongruent phylogenetic trees, in which phylogenies inferred on either side of a recombination breakpoint differ significantly in topology, reflecting the contrasting evolutionary histories of these gene regions. Although such phylogenetic approaches can be biased in two ways—false positives caused by mixed infection or experimental error²¹ and that tree-based methods only detect recombination when there is measurable sequence diversity—they represent a simple means to detect recombination in a wide range of viruses and in doing so allow a direct comparison of recombination frequency.

Mechanisms of recombination differ markedly between viruses, reflecting the very different types of replication strategy employed, although all require co-infection of a single cell by two or more viruses. In the case of dsDNA viruses, recombination

likely occurs in a manner analogous to that observed in other DNA-based organisms, although the precise mechanisms of recombination are not known in all cases. Hence, recombination will involve the occurrence and repair of double-stranded breaks and, in the case of large dsDNA viruses, the presence of multiple recombination enzymes.¹⁰⁵ Recombination appears to be particularly commonplace in poxviruses, an apparent outcome of the form of DNA strain invasion used in replication,^{63,64} as well as in herpesviruses.²³ Recombination in large DNA viruses can be both homologous, in that it occurs at regions exhibiting strong sequence identity, and nonhomologous, involving divergent gene sequences (usually occurring as lateral gene transfer) and can occur at the intra- and interspecific levels.²¹⁹ It therefore plays a major role in shaping genomic architecture.¹⁵¹ For example, in poxviruses recombination may be more commonplace at the extremities of the genome, as these contain most of the species-specific genes, than in the central genomic regions that are conserved among viruses.^{62,151} Rather less is known about the mechanics of recombination in ssDNA viruses, although it is likely to occur as a consequence of the rolling circle replication employed by these viruses,¹⁹⁹ which may both determine the distribution of recombination breakpoints²²³ and result in frequent genome rearrangements, as in the case of Torque teno (TT) virus.¹³³

Evolutionary aspects of recombination are better studied in RNA viruses. Recombination in this case occurs by two rather different mechanisms. The first, sometimes called RNA recombination, occurs when two viruses co-infect a single host cell and a hybrid molecule is produced, most likely through a process of *copy-choice replication*,¹²⁷ although other mechanisms have been proposed. Under the copy-choice model the viral polymerase is thought to jump templates during negative strand synthesis, generating a chimeric RNA molecule.¹²⁷ Although this process is usually homologous, template switching can also occur among genomic regions that do not share sequence similarity. In theory, RNA recombination can occur in any type of RNA virus, irrespective of their genome structure

or orientation, although rates vary hugely among viruses (see later). The second process of recombination in RNA viruses is reassortment, which only occurs in RNA viruses that possess segmented genomes, such that a progeny virus packages segments with different ancestries. Rates of reassortment also vary markedly among RNA viruses, from very frequent in the case of influenza A virus¹⁸² to far less so in the case of hantaviruses.¹⁶⁵

Clearly, recombination can be of great evolutionary importance for viruses²¹¹ and has been associated with such features as the evasion of host immunity,¹⁴¹ the development of antiviral resistance,¹⁶⁶ the ability to infect new hosts,⁹⁶ increases in virulence,¹¹⁸ and even the creation of new viruses.²²⁷ As a consequence, it is important to document cases of viral recombination and reveal the determinants of this process. However, the occasional occurrence of beneficial traits arising from recombination does not necessarily mean that recombination evolved for this purpose, as recombination is as likely to break up beneficial genotypic configurations as create them. Indeed, explaining why recombination has evolved is one of the outstanding questions in evolutionary biology.

For viruses, clues for the reasons underlying the evolution of recombination are provided by the huge variation in recombination rates, from effectively clonal (i.e., asexual) to cases in which the recombination rate per nucleotide exceeds that of mutation. This extensive rate variation is particularly true of RNA viruses. The most common theory for the evolution of recombination is that it functions as a form of sexual reproduction in viruses and as such has been selectively optimized to either create advantageous genetic configurations or remove deleterious mutations (Fig. 11.10). However, this seems unlikely on first principles as high rates of recombination are only seen in a relatively small fraction of virus taxa, such that high recombination rates cannot be universally advantageous.²¹¹ This patchy distribution sits in marked contrast to theories for the evolution of sex in eukaryotes, the aim of which is to explain common recombination and sporadic asexuality.¹⁸⁹ Similarly, the patchy distribution of recombination

Evolutionary Benefit of Recombination

(1) Creation of beneficial genotypes:

Recombination increases the rate of adaptive evolution compared to clonal evolution. It also disassociates advantageous from deleterious mutations, allowing the former to spread.

(2) Purging of deleterious mutations:

Recombination enables deleterious mutations to be placed into a single genome which can be removed by purifying selection. This can be selectively favored if deleterious mutations occur at a high rate (i.e. $U > 1$) and interact through synergistic epistasis.

Schematic Representation

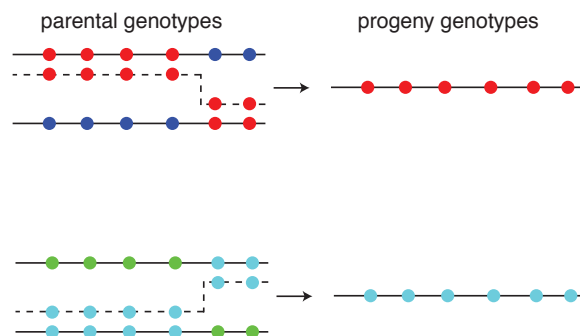

FIGURE 11.10. Potential evolutionary benefits of viral recombination (and reassortment) that might be favored by natural selection and that are commonly invoked in discussions of the evolution of sex. Accordingly, recombination can either (1) create advantageous genetic configurations (red circles), and also disassociate advantageous from deleterious mutations, or (2) purge deleterious mutations (green circles) by placing them in a single individual, which can be removed by purifying selection. In both cases the hatched line denotes the recombination event. (Adapted from Simon-Loriere E, Holmes EC. Why do RNA viruses recombine? *Nat Rev Microbiol* 2011;9:617–626, which should be consulted for more details.)

means that it is unlikely to universally have evolved as a form of repair.¹⁵³

It is obvious that recombination allows viruses to create potentially beneficial genetic configurations more rapidly than asexual populations, and there are many documented cases in viruses in which recombination has been associated with the generation of advantageous characteristics, such as drug-resistant genotypes. However, there are a number of viruses where rates of recombination are very low but where adaptive evolution is extremely common, with hepatitis C virus (HCV) a good case in point.¹⁸⁸ Hence, it may be that RNA viruses create a sufficient number of beneficial genotypes through mutation alone to offset the need for recombination. Recombination has two other important consequences for adaptive evolution. First, it disassociates advantageous from linked deleterious mutations,¹⁸⁹ and second, it prevents *clonal interference*. The latter describes a competition between beneficial mutations as they go to fixation in asexual populations, such that their rate of adaptation is retarded compared to that of sexual populations. Although both these processes are likely to occur in virus populations,¹⁵⁵ their overall importance is unclear.

The second advantage of recombination over purely clonal evolution is that it facilitates the efficient removal of deleterious mutations. This is often called the *mutational deterministic hypothesis* and is a hotly debated theory for the evolution of sex in a wide range of species.^{117,122} The central idea is that rather than many individuals (or genomes) carrying deleterious mutations, which would have a major negative impact on fitness, recombination allows these injurious mutations to be placed in a single individual whose selective removal greatly reduces fitness costs. A related theory is that of Muller's ratchet, which describes a progressive decrease in fitness due to the gradual accumulation of deleterious mutations in asexual populations of finite size and where genetic drift accelerates the loss of mutation-free individuals. Muller's ratchet has been observed in laboratory populations of RNA viruses^{34,35,50} and may therefore play some role when clonal viruses experience small population sizes, such as during transmission bottlenecks, although its effects are likely to be negated when viruses reach large population sizes.

For the mutational deterministic hypothesis to explain the origin of recombination, it is essential that the deleterious mutation per genome replication (U) is greater than 1, and hence very high, and that these deleterious mutations interact through synergistic epistasis.¹²² For RNA viruses $U > 1$ may be attained relatively regularly.^{52,61} This may also be true of ssDNA viruses, which similarly possess small genomes and genes that encode multiple overlapping reading frames and functions. Unfortunately, there are currently no estimates of U in large DNA viruses. However, there is little good evidence for synergistic epistasis in RNA viruses, with most studies undertaken to date suggesting that epistatic interactions are antagonistic rather than synergistic.^{20,28,197} In contrast, the greater genetic redundancy in large DNA viruses makes antagonistic epistasis a more likely occurrence in this instance. In addition, sequence comparisons suggest that the burden of deleterious mutation is high for all RNA viruses studied, irrespective of background recombination rate.¹⁸¹ Hence, it is not recombination that saves RNA viruses from an excessive mutational load, but rather their large population sizes that provide a form of *population robustness* that offsets the effects of deleterious mutation.⁵⁸

An opposing theory for the evolution of viral recombination is that rather than being optimized by natural selection as a form of sexual reproduction, it is simply a mechanistic by-product of differing types of genome architecture, replication strategy, and polymerase processivity.²¹¹ The principal evidence for this theory is that there is an apparent association between recombination frequency and virus genome structure. Hence, recombination is relatively frequent in some retroviruses, and as is reassortment in viruses with segmented genomes. Far more variable recombination rates are observed in ssRNA+ viruses, for example, frequently in coronaviruses and enteroviruses, sporadically in flaviviruses, and currently absent in *Leviviridae* and *Narnaviridae* (although this may be a function of sample size). Finally, recombination is far less common in ssRNA- viruses. A simple example of the disparity of recombination rates is provided by a comparison of HIV-1 and HCV. In the former, recombination rates have been estimated at between 1.38×10^{-4} and 1.4×10^{-5} recombination events per site, per generation,^{164,207} while the equivalent estimates for HCV are only 4×10^{-8} .¹⁸⁸ The low rate in HCV means that recombination is unlikely to be of great evolutionary significance for this virus. Most DNA viruses studied to date seem to experience relatively high levels of recombination (including through lateral gene transfer in the case of large DNA viruses), although there have been few attempts to estimate rates of recombination relative to those of mutation.²³ One DNA virus in which recombination has been particularly well studied is HBV, along with related hepadnaviruses. In this case recombination is commonly depicted using phylogenetic methods and likely represents one of the main reasons that the evolutionary history of this virus has been so hard to determine.²⁰⁸

In each case mentioned previously the frequency of recombination seems to reflect the genome structure of the virus in question.²¹¹ Hence, the high recombination rates of retroviruses are likely a function of the fact that their virions carry two RNA molecules, such that *heterozygous* progeny will be produced when viruses with different ancestries are packaged together. Copy-choice recombination, which is common in this virus, may then produce genetically distinct progeny during reverse transcription. However, not all retroviruses recombine at the same rate as HIV. For example, recombination rates in murine leukemia virus (MLV) are up to 100 times lower than those observed in HIV, despite very similar rates of template switching. The difference between these two viruses is that while HIV genome dimerization occurs randomly in the cytoplasm, genome dimerization in MLV takes place in the nucleus and generally leads to self-associations, rather than to those involving genetically different parental molecules.¹⁷⁰

That heterozygous viral progeny cannot be produced when the genomic material is present as a single molecule obviously acts to reduce recombination rates in most RNA viruses. However, in some cases specific genome organizations can facilitate frequent recombination. Case in point are the coronaviruses, such as murine hepatitis virus (MHV), where up to 25% of the progeny of co-infected cells may be recombinant. Such a high recombination rate reflects the mechanisms controlling gene expression in coronaviruses, in which discontinuous transcription leads to the production of subgenomic RNAs through a copy-choice mechanism.¹⁹⁸ An even more dramatic example of how replication strategy and genome organization may shape recombination rate occurs in the ssRNA- viruses, in which

recombination is relatively infrequent. In these viruses the genomic and antigenomic RNA molecules are quickly bound to multiple nucleoprotein subunits, as well as to other proteins, to form ribonucleoprotein (RNP) complexes from which viral replication and transcription can proceed. However, this tight complex of RNA and protein necessarily limits the probability of hybridization of complementary sequences between the nascent and acceptor nucleic acid molecules, and hence the probability of template switching, and also reduces the potential number of substrates for this process.²¹¹ Accordingly, those phylogenetic studies undertaken to date have revealed relatively few cases of recombination in ssRNA– viruses.^{7,231}

The RNA Virus Quasispecies

One of the most contentious issues in the study of virus evolution is whether RNA viruses evolve according to a particular population genetic model known as the *quasispecies*.⁹² In some aspects, this debate merely reflects a semantic point about how best to describe the intrahost genetic variation commonly seen in RNA viruses. However, a far more important issue, and the true essence of the quasispecies debate, is how natural selection acts on virus genomes.

Quasispecies theory was originally developed by Manfred Eigen and colleagues as a model of the evolution of self-replicating RNA molecules that likely represent the first replicators.^{56,57} The theory was first applied to RNA viruses after genetic variation was observed in a number of experimental systems, beginning with the bacteriophage $\phi\beta$.⁴⁶ Since this time the quasispecies has become a popular descriptor of intrahost RNA virus evolution, particularly because widespread gene sequencing has uncovered abundant genetic diversity. However, because the theory is based on high mutation rates (see later), it should not be applied to large DNA viruses where error frequencies are lower.

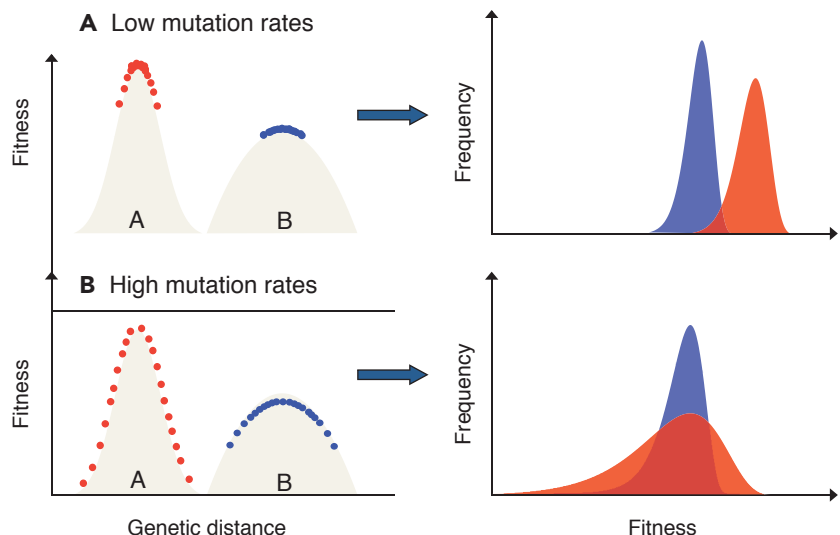

Although commonly used simply as a synonym for genetic variation, quasispecies in fact describes a specific type of mutation-selection balance. Mutation-selection balances are commonly invoked in population genetics and describe an evolutionary equilibrium between the generation of new mutations and their removal by purifying selection. The form of

mutation-selection balance invoked in quasispecies theory is based on the occurrence of an extremely high mutation rate, which ensures that the frequency of any variant in the population is a function of both its individual fitness *plus* the frequency at which it is produced by the erroneous replication of other variants in the population that are linked to it in mutational space. This *mutational coupling* means that viral genomes are not independent entities, such that natural selection favors the entire population as opposed to individual variants. In this manner the group, rather than the individual, becomes the unit of selection.⁵⁷

The central tenet of quasispecies theory is thus that natural selection acts on the viral population as a whole, rather than on individual variants. As a consequence, the entire quasispecies evolves to maximize its average fitness, rather than that of individual variants as is the case in other population genetic models. The most interesting outcome of this particular evolutionary process is that low fitness variants can sometimes outcompete those of higher individual fitness if the former are surrounded by beneficial mutational neighbors. This is sometimes referred to as the *quasispecies effect* or the *survival of the flattest*²³⁰ and describes a situation in which a population whose component mutants have a similar mean fitness can outcompete a population that has a lower average fitness even though it contains variants of higher individual fitness. Under classic *survival of the fittest* population genetic models, these individual high-fitness variants are selectively favored, whereas under *survival of the flattest* (i.e., quasispecies) models, the flatter population is selectively superior as it possesses a higher mean fitness (Fig. 11.11). This can also be thought of as a form of mutational robustness.

A key component of quasispecies theory is that intrahost populations of RNA viruses harbor abundant genetic diversity. There is no doubt that this specific aspect of quasispecies theory is correct, and even so for acute infections, as intrahost genetic variation is commonly observed in RNA viruses.^{44,92} In particular, studies using next-generation sequencing, in which the sequencing coverage of individual nucleotides is very high, have revealed extensive genetic diversity, with HIV-1⁶⁹ and foot-and-mouth disease virus (FMDV)²³⁴ serving as good examples.

FIGURE 11.11. The quasispecies effect (*survival of the flattest*) in experimental populations of RNA viruses. The red population (A) has a high replication rate (i.e., fitness) but low mutational robustness, while the blue population (B) has a lower replication rate but greater mutational robustness. Dots depict mutational variants located on each peak at low and high mutation rates, and the expected distribution of individual fitness values for the two populations is shown on the **right** of the figure. At low mutation rates, population A will always outcompete the flatter population B as it contains the variant of highest individual fitness. However, at very high mutation rates natural selection favors the flatter population (B) as predicted under quasispecies theory. (From Sanjuán R, Cuevas JM, Furió V, et al. Selection for robustness in mutagenized RNA viruses. *PLoS Genet* 2007;3:e93.)

However, a very important caveat is that many estimates of intrahost genetic diversity are likely to have been inflated by erroneous polymerase chain reaction (PCR) and sequencing.¹⁴⁰ Indeed, RT-PCR is a notoriously error-prone process, with artificially induced mutations an inevitable consequence, and different sequencing systems are also characterized by specific error rates. In addition, intrahost genetic diversity in nature is not simply the product of *de novo* mutation because the mixed infection of individual hosts may also play an important role in shaping levels of intrahost genetic variation (see later). More importantly, although the observation of intrahost genetic variation is a necessary criterion for an RNA virus population to be thought of as a quasispecies, it is not sufficient in itself as intrahost genetic diversity is expected under any evolutionary model if the mutation rate is high enough. The quasispecies is therefore not simply another word for intrahost genetic variation.

Both *in silico* and *in vitro* studies have provided some evidence for the existence of quasispecies dynamics defined correctly. As an example of the former, computational studies using *digital organisms* revealed that the survival of the flattest could be induced at very high mutation rates.^{40,230} However, as the mutation rates involved were always higher than one mutation per genome replication, it is uncertain whether such mutation rates could ever be attained for sustained periods in RNA viruses in nature. Similar results have been obtained from some experimental analyses of RNA virus evolution. Studies using both viroids of plants and VSV showed that viral populations with lower replication rates were able to outcompete those with higher replication rates, as expected under the quasispecies model, although this again requires the elevation of mutation rate (by either chemical mutagens or ultraviolet C light) to levels that may not commonly occur in RNA viruses in nature.^{38,193} Additional experimental evidence for the existence of RNA virus quasispecies was the observation that high-fitness clones of bacteriophage $\phi 6$ evolved to a lower mean fitness because their mutational neighbors were of low fitness,²⁷ and that strains of poliovirus that possessed higher fidelity than the wild type, such that the virus population carried less genetic diversity, were unable to infect the full range of tissues that are associated with severe disease.²²⁴ This in turn suggested that quasispecies dynamics might be a central determinant of viral pathogenesis.²²⁴

Another class of experimental studies that have been cited in support of the quasispecies model involves lethal mutagenesis. This entails treating virus populations with mutagens, such as 5-fluorouracil and ribavirin, that increase the error rate to the extent that so many deleterious mutations are produced that fit genotypes are never able to regenerate themselves. Although lethal mutagenesis can clearly result in virus extinction, especially if mutagens are used in combination with more standard antiviral inhibitors,^{4,171} the basis of this effect is more complex. Quasispecies theory predicts that virus extinction in this instance occurs because of an *error catastrophe*, which is the point at which the fittest genotype suffers so many deleterious mutations that it cannot sustain itself in the population (i.e., it has breached an *error threshold*). However, another interpretation is that the virus has instead crossed an *extinction threshold*, the point at which deleterious mutations accumulate faster than they can be eliminated by natural selection, which will also lead to population extinction.²⁶ Importantly, error catastrophe

requires a fundamental shift in viral genotype that is independent of population size, whereas extinction threshold entails a major decline in viral population size.

Studies of RNA virus evolution based on the comparative analysis of gene sequence data have provided less support for the existence of quasispecies. Indeed, there is currently no clear evidence that selection acts on groups rather than individual variants in natural populations of RNA viruses, although this may reflect the fact that even with the most sophisticated tools of gene sequence analysis it is difficult to discern the effects of all but the most strongly favored and disfavored variants. For example, although natural selection is very commonly documented in HIV, the adaptive process always seems to involve the fitness advantage of individual mutants over others in the population, rather than group selection. Similar points can be made for other RNA viruses.⁹² Again, though, it is arguable that natural selection is so strong in these cases as to obscure any quasispecies effect, and that the latter model is a far better description of mutations subject to weaker positive selection, as most natural selection will be in nature. This is clearly a major area for further study.

To conclude, given a sufficiently high mutation rate, quasispecies is a viable and extremely interesting evolutionary model. However, it is less clear whether the quasispecies concept can be successfully applied to RNA viruses in nature, where to date there has been no convincing evidence for its occurrence. This does not necessarily mean that the quasispecies model is wrong, but rather that too few RNA viruses have been studied in sufficient detail through deep amplicon sequencing and precise fitness assays to determine whether they form quasispecies, exemplified by a process of natural selection acting on the virus population as a whole.

PATTERNS AND PROCESSES OF VIRAL GENOME EVOLUTION

The Evolution of Virus Genome Size

Viruses possess a remarkable range of genome sizes (Fig. 11.12). This is especially so for DNA viruses in which genome sizes range from only 1,758 nt in *Porcine circovirus* (ssDNA) to a remarkable 1,259,197 nt in the case of the megavirus *Megavirus chilensis* (dsDNA),⁹ hence covering approximately three orders of magnitude, although all ssDNA viruses have genomes less than 11,000 nt in length. A far narrower range of genome sizes is observed in RNA viruses. The smallest RNA virus currently known is *Ophiostoma novo-ulmi* *mitovirus* 6-Ld, at only 2,343 nt, while the largest RNA viruses are the coronaviruses and roniviruses (order *Nidovirales*), which have genome sizes of approximately 30,000 nt. Mean genome sizes in RNA viruses are around 10,000 nt. Interestingly, there does not appear to be a major difference in genome size between segmented and unsegmented RNA viruses,⁹² with, for example, the unsegmented *Coronaviridae* and *Roniviridae* possessing larger genomes than all segmented RNA viruses. This strongly suggests that genome segmentation has not evolved as a way to increase virus genome sizes.

A variety of theories have been proposed to explain the evolution of genome sizes in viruses. One theory is that virus genome sizes are constrained by the maximum size of the

FIGURE 11.12. Distribution of genome sizes in RNA and DNA viruses. Note the similarity in (small) genome sizes between RNA viruses, retroviruses, and single-stranded DNA (ssDNA) viruses.

genetic material that can be contained within a single capsid protein.²³⁸ However, the huge range of genome sizes, especially in DNA viruses, argues against this. The genome content of large DNA viruses in part reflects often frequent lateral gene transfer and gene duplication (see later). In particular, the central part of the genome of many large DNA viruses is composed of a set of core genes that control basic biochemical functions, including replication, while the outer, flanking genes distinguish individual viruses and are often responsible for modulating immunity, host range, and virulence, and it is these that have often been captured from host genomes. This process of gene birth and death has resulted in a great variation in genome sizes, with, for example, a massive increase in genome size from the ancestral NCLDV to those circulating today.¹⁰⁵ This evolutionary process, combined with the discovery of the giant viruses of algae and amoeba, suggests that there are unlikely to be strict constraints against genome sizes in large DNA viruses. Similarly, that bacteriophages are able to transiently carry large parts of bacterial genomes, which evidently plays a key role in lateral gene transfer among bacterial species,¹⁶⁹ also argues against strict constraints on genome size.

However, it is also the case that certain structural features must constrain genome sizes to some extent. First, longer viral genomes are expected to cause an increase in replication times, which may be disadvantageous. Second, in the case of RNA viruses, it is possible that the difficulty in unwinding potentially long regions of dsRNA during replication inhibits the maximum genome size attainable.¹⁸⁶ For example, it has been argued that the unwinding of dsRNA in RNA viruses with genomes greater than 6,000 nt is controlled by the presence of a helicase (HEL) domain,⁸³ the evolution of which allowed RNA viruses to greatly increase their genome size.⁸²

A more plausible explanation for the range of viral genome sizes is that they reflect background mutation rates. As noted previously, there is a fundamental relationship between mutation rate and genome size that seemingly applies to all living systems (Fig. 11.6). Accordingly, dsDNA viruses with relatively low mutation rates will be able to attain relatively large genome sizes, while the small genomes observed in RNA and ssDNA viruses reflect the higher error rates seen in these systems. Perhaps paradoxically, the idea that mutation rates set genome size can be extended to explain the very large (by RNA virus standards) genomes seen in the coronaviruses and roniviruses. The major part of the genomes of these families is composed of a large (greater than 20,000 nt) replicase gene that contains

an ExoN domain encoding a 3' to 5' exoribonuclease. As this ExoN domain is homologous to cellular proteins of the DEDD superfamily of exonucleases that are involved in proofreading and repair,¹⁵⁴ it is possible that coronaviruses and roniviruses reduce their error rate through some sort of proofreading activity of the 3' to 5' exoribonuclease.⁵³ This, in turn, will reduce mutational load and allow larger genome sizes.

A final important difference between RNA and dsDNA viruses with respect to genome size is that the former (as well as ssDNA viruses) frequently utilize overlapping open reading frames, whereas these are less common in the latter (although, for example, the M065R and M066R genes of the poxvirus myxoma virus overlap by ~100 bp). Belshaw et al.¹² noted 819 cases of gene overlap among 701 RNA virus genomes; 56% of the viruses examined possessed some degree of overlap, which nearly always involved a +1 or -1 frame shift. In addition, RNA viruses with longer genomes tend to show less gene overlap than those with shorter genomes.¹² Although the exact evolutionary processes responsible for the evolution of overlapping reading frames are uncertain, they clearly allow an increase in the amount of protein diversity encoded by a single nucleotide sequence.

The Evolution of Genome Organization

It is arguable that viruses contain a greater diversity of genome structures and organizations than any other group of organisms. As well as the obvious division into RNA viruses, DNA viruses, and retroviruses, distinct genome structures include viruses in positive and negative sense orientations, those with single or double strands of the nucleic acid, those with single or multiple segments (which are usually multicomponent in the case of ssRNA+ viruses from plants), those that utilize subgenomic RNAs, and those like the coronaviruses that utilize ribosomal frame shifting. A key challenge for evolutionary virologists is therefore to explain why such a diverse array of structures exists.

One of the most debated issues with respect to the evolution of genome structures in RNA viruses is why some are segmented and others not. As noted previously, one theory for the evolution of segmentation is that it evolved as a way of facilitating reassortment, although this seems unlikely.²¹¹ Similarly, there is no good evidence that segmentation allows the evolution of longer genomes. Another possibility is that genome segmentation, particularly in multicomponent viruses, resulted from the intracellular selection for smaller RNAs that,

because they are shorter, would have had a replication advantage over their full-length counterparts.¹⁶³ However, this theory cannot easily explain why multicomponent viruses are nearly all restricted to plants.

A competing theory for the evolution of genome segmentation is that it allows greater control over gene expression. Clearly, all RNA viruses need to control the levels of each protein they produce. For many ssRNA+ viruses such control occurs at the level of translation as this is necessarily the first step in the virus life cycle. Additional constraints faced by viruses of this type are that eukaryotic ribosomes only recognize the 5' regions of mRNA molecules, so that internal start codons are not utilized, and mRNAs are usually monocistronic.⁹² Many ssRNA+ viruses therefore simply translate a single polyprotein that is proteolytically cleaved into individual protein products, which may represent the ancestral type of genome organization in ssRNA viruses. Although this genomic structure allows efficient replication, similar amounts of each protein product are produced, so that there is relatively little control over gene expression. As a consequence, other ssRNA+ viruses have evolved a variety of more complex ways to control gene expression, all of which can be envisioned as ways of

dividing the viral genome into individual *transcriptional units*, within which transcription (and translation) can occur at different rates. Such a division can involve the creation of multiple genome segments, the utilization of subgenomic RNAs, and the use of a –1 ribosomal frameshift to produce multiple open reading frames as in the case of the coronaviruses and roniviruses⁹² (Fig. 11.13).

The situation is rather different in the case of ssRNA– viruses. Because ssRNA– viruses by necessity transcribe their genomes before translating them, some control over gene expression can occur at the level of transcription; multiple mRNAs can be produced and there will be a transcriptional gradient from the first (i.e., 3') mRNA, of which most is produced, to the last (5') mRNA, of which least is produced. It is therefore possible that the ability to better control gene expression, itself through the control of transcription, represents the reason that negative-sense genomes evolved in the first instance. In this respect it is significant that the genomes of unsegmented ssRNA– viruses possess a highly conserved gene order, cluster together on polymerase phylogenies, and can easily be classified within the *Mononegavirales*. Moreover, this genome order seems to be a function of the amount of each

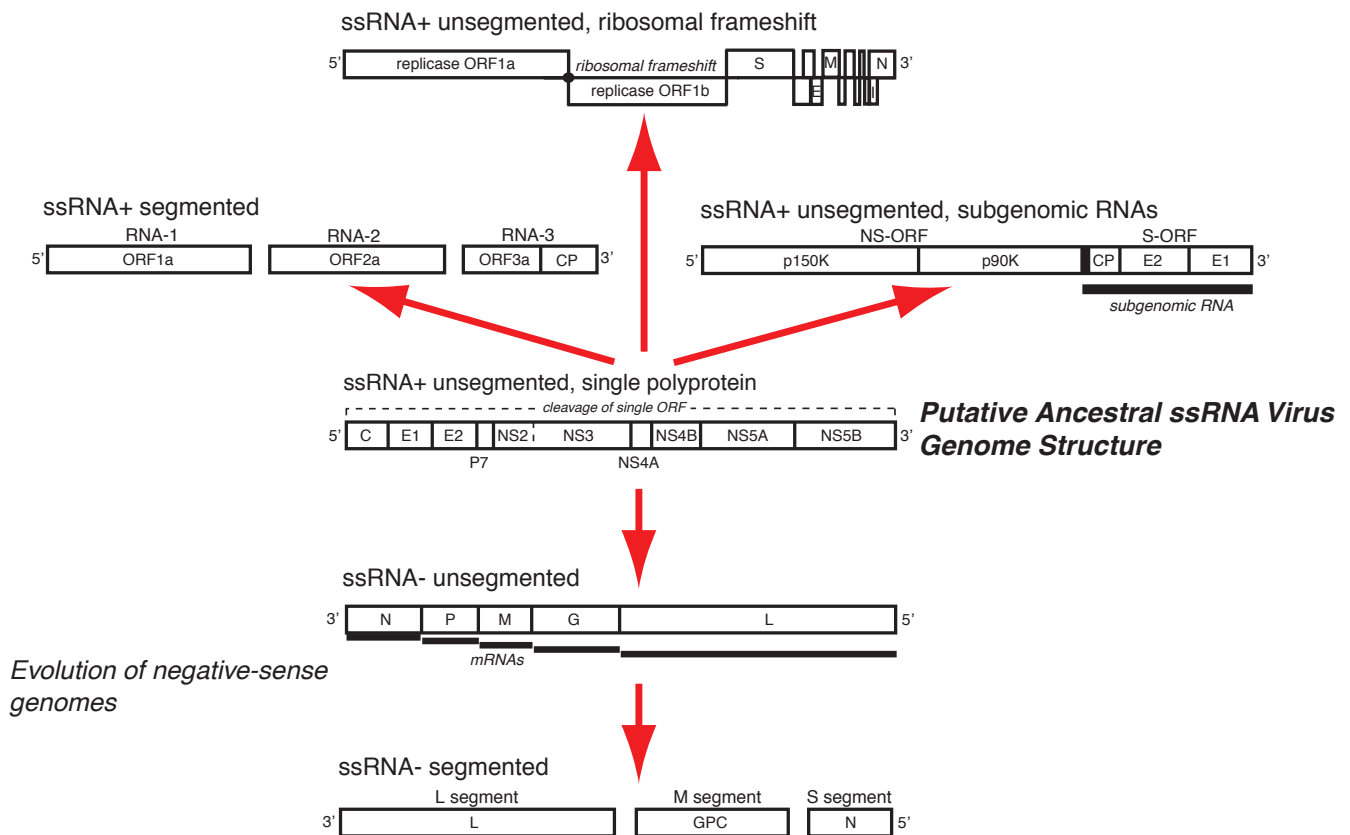

FIGURE 11.13. Schematic representation of the major types of genome organization and replication strategy in RNA viruses and a scenario for their evolutionary origin. Each of these organizations results in a different way to control gene expression, although they should not be considered as mutually exclusive. Unsegmented single-stranded RNA-positive (ssRNA+) viruses that produce a single polyprotein are considered here to be the ancestral type, although this is debatable. Gene and segment sizes are drawn approximately to scale within each of the six organizations, but not among them, and the 5' and 3' terminal sequences have been excluded. (From Holmes EC. *The Evolution and Emergence of RNA Viruses*. Oxford: Oxford University Press, 2009, by permission of Oxford University Press.)

protein product required, such that the 3' gene encodes the nucleocapsid while the 5' gene encodes the RNA polymerase, again suggesting that it is an adaptation to facilitate the control of gene expression.

Gene Duplication in Virus Evolution

One of the most important processes of genome evolution in eukaryotes is gene duplication. This represents an important way in which these organisms create evolutionary novelty; gene duplication is a simple way to create new genes that, following subsequent mutation and adaptation, can exhibit different but related functions, which often appear as multigene families. Because of the evolutionary importance of gene duplication in molecular evolution, it is important to determine its frequency in viruses. Such an analysis again reveals a major division between RNA and ssDNA viruses on the one hand and large dsDNA viruses on the other.

While gene duplication must be responsible for at least some of the genome size variation observed in RNA viruses, particularly during their early evolution, it is striking how rarely this process has been observed in RNA viruses.⁹² An important caveat to make here is that because RNA virus evolution is so rapid and phylogenetic signals lost so quickly, it is possible that gene duplication has occurred more frequently in the past but that the footprints of this process are hidden by frequent multiple substitution. Those gene duplication events documented thus far in RNA viruses tend to occur as short duplications in untranslated or intragenic regions and often result in defective viruses.²⁹ Only occasionally have gene duplication events been described that produce two complete (and sometimes tandemly repeated) genes,^{24,225} although improvements in computational analysis are likely to reveal more. The difficulties in analyzing divergent sequences notwithstanding, there are good reasons for the relative rareness of gene duplication in RNA (and ssDNA) viruses. In particular, given the size limit on virus genome discussed throughout this chapter, increasing genome size through gene duplication is likely to result in major fitness losses through an increase in the load of deleterious mutations.

The situation is very different in large dsDNA viruses, where cases of gene duplication, as well as gene loss, are a common observation and are evidently responsible for some of the size variation among viruses^{100,200} (Fig. 11.14). Gene duplication can occur in both the core and species-specific genes of

large DNA viruses as signified by the presence of related gene pairs and multigene families.¹⁴⁹ For example, gene duplication has been commonplace in the E4 region of some adenoviruses⁴³ and in the terminal inverted repeats of the poxvirus myxoma virus,¹²⁶ although many other examples exist. The process of gene duplication may also be related to that of recombination. For example, in some poxviruses recombination seems to have resulted in the duplication, inversion, and transposition of genes to opposite ends of the genome.¹⁶¹ Finally, the analysis of protein structure suggests that some of these gene duplication events may have occurred in the distant past and assisted in the production of very distinct proteins, such as the head–tail connector protein and tail tube protein of bacteriophage lambda.³⁰

Lateral Gene Transfer and Modular Evolution

A major way for bacteria to create evolutionary novelty is through lateral (or horizontal) gene transfer (LGT), which can sometimes result in genes being transferred for large phylogenetic distances.¹⁶⁹ As LGT will also result in an increase in virus genome size, unless the original gene is directly replaced by the invading gene (which is unlikely unless an exact excision is made, as faulty excision will result in deleterious mutants), it is not surprising that this process has to date only been rarely described in RNA viruses and ssDNA viruses, although it is again important to recall that inferences are compromised by extreme phylogenetic distance. One well-documented case of LGT in an RNA virus involves the acquisition by influenza C virus of the hemagglutinin-esterase (*HE*) gene of coronaviruses.¹³⁹

Lateral gene transfer can occur among viruses and between viruses and hosts. In the case of RNA viruses there are sporadic reports of these infectious agents transiently incorporating host genome sequences. A famous example is provided by the integration of ubiquitin into the genomes of bovine viral diarrhea virus.¹⁵² Similarly, the sequence similarity between the 65-kD protein of closteroviruses (ssRNA+) and the cellular heat shock protein hsp70² may indicate an early LGT event, while the capture of the ExoN domain by coronaviruses has been discussed in more detail earlier. In reality, however, there are few reports of the stable integration of cellular sequences into the genomes of RNA viruses, although more are likely to be documented with the acquisition of increasing numbers of host genome sequences.

In contrast, the capture of host genes is very well documented in the case of large DNA viruses, including those from

FIGURE 11.14. Processes of lateral gene transfer, from both hosts and other viruses, and gene duplication in large double-stranded DNA (dsDNA) viruses. Core viral genes, which are conserved across divergent taxa, are shown in red and often located in the central part of the genome. Genus and species-specific genes are shown as white and yellow, respectively, and more often located at the terminal regions of the genome. Refer to Figure 11.15 for a real data example. (Adapted from Shackelton LA, Holmes EC. The evolution of large DNA viruses: combining genomic information of viruses and their hosts. *Trends Microbiol* 2004;12:458–465.)

FIGURE 11.15. Comparative genomics of poxviruses. The figure shows a comparison of 92 gene families from 20 different poxviruses. Genes present in all the poxviruses analyzed are shown in red and are located in the central genomic regions. Those genes present in chordopox viruses only are shown in blue, while those present in orthopoxviruses only are shown in yellow. Vertical lines link orthologous genes. Horizontal differences are drawn proportional to genetic distances. (From McLysaght A, Baldi PF, Gaut BS. Extensive gene gain associated with adaptive evolution of poxviruses. *Proc Natl Acad Sci U S A* 2003;100:14960–14965. Figure kindly provided by Aoife McLysaght.)

both bacteria¹⁷³ and eukaryotes,¹⁰⁵ although the complex phylogenetic shadows cast by gene birth and gene loss means that it is sometimes difficult to determine from which host species and when these gene transfer events occurred. The poxviruses have been very well studied in this respect, with the interleukin-10 (*IL-10*) gene family and the vertebrate vascular endothelial growth factor (*VEGFA*) genes, which are distributed among both poxviruses and a range of vertebrates, as well as the DNA ligases, acting as good examples (and the *IL-10* family is also observed in herpesviruses).^{25,102,151} In fact, LGT is a common occurrence in all NCLDV and covers an enormous taxonomic range of hosts.^{66,105} For example, mimivirus may have acquired perhaps 10% of its total gene content from bacterial species, including a number of mobile genetic elements.⁶⁴ In poxviruses gene content seems to change more rapidly than gene order, reflecting the fact that species-specific genes tend to get added to the extremities of genomes (Figs. 11.14 and 11.15). That the flanking genes of large DNA viruses are often the ones captured by the host in turn suggests that internal gene orders are optimized to the extent that disrupting them may result in major fitness losses. Similarly, human herpesviruses contain homologs to such important immune genes as those that encode cytokines, chemokines, and complement system proteins, as well as those of the immunoglobulin superfamily.^{145,183} These genes may modulate the immune response of the host, often by interfering or mimicking their cellular homologs. However, it is not only host immune genes that are acquired by dsDNA viruses. As a case in point, iridoviruses encode a number of cellular proteins that seem essential for virus replication.²²⁰

It is also the case that LGT has occurred among large DNA viruses and is particularly well documented in bacteri-

ophage, where it appears to be a common mode of molecular evolution⁸⁶ (and phage-mediated LGT is of course a key process of bacteria evolution¹⁶⁹), as well as in a number of eukaryotic viruses.⁴³ As another example, the entomopoxvirus *Amsacta moorei* virus (AMV) contains a number of genes that have been acquired from baculoviruses.¹⁰⁵ However, as with the case of LGT among viruses and hosts, it is often hard to pinpoint the exact origin and direction of any gene transfer event.

Less clear is exactly how viruses capture host genes. Although such an event could obviously occur through direct recombination, this would require entry into the nucleus and would result in virus genes containing introns. An alternative possibility is that complementary DNA (cDNA) copies of spliced cellular mRNAs, which do not contain introns, have been inserted into virus genomes, perhaps utilizing the RTs present in cellular retroelements.²⁰⁰ On the other hand, LGT that occurs among viruses, or between viruses and bacteria, most likely occurs during host co-infections.

One of the most interesting developments in studies of virus evolution in recent years is the observation of segments of RNA virus genomes incorporated into host cellular genomes. For retroviruses that make dsDNA and enter the cell nucleus, as well as small ssDNA viruses that are so restricted in size that they do not carry their own polymerase genes and similarly must enter the cell nucleus, the presence of these integrated virus genes is perhaps not a surprise. Indeed, it has been known for many years that much of the eukaryotic genome was composed of endogenous retroviruses.^{18,228} More surprising was the discovery that RNA viruses, which do not make a DNA genomic copy and often replicate in the cytoplasm, could also become integrated into host genomes (in the form of EVEs; see earlier). The first clear-cut case of virus-to-host

LGT to be documented involved sequences closely related to those of insect flaviviruses and found to be integrated into the genomes of *Aedes* mosquitoes.⁴² Since this time a number of other examples have been discovered, including bornavirus,⁹⁷ filoviruses,²¹⁸ and rhabdoviruses,¹¹³ often comprising a very wide range of hosts.⁹⁴ Similarly, EVEs have also been documented in a number of small DNA viruses, including circoviruses, parvoviruses,^{15,111,136} and hepadnaviruses.⁸⁰

As noted at the start of this chapter, the presence of these endogenous virus elements has changed our perspective of the time scale of virus evolution, indicating that some virus families may be far older than previously anticipated. However, these sequences raise other interesting questions, most notably by what mechanisms single-stranded RNA is converted into double-stranded DNA. The most plausible answer involves interaction with the cellular retroelements that are an abundant component of eukaryotic genomes, with the L1 long interspersed nucleotide elements a notable example⁹⁷ (Fig. 11.4). In addition, some EVEs appear to be more conserved than expected if they were evolving in a strictly neutral manner, free of all selective constraints.¹¹³ As such, some of these endogenous virus copies may be of functional importance, perhaps because they confer resistance against related exogenous viruses.⁸

Finally, one process of genome evolution that is mechanistically similar to that of lateral gene transfer, and that has been of great historical importance in studies of virus evolution, is that of *modular evolution*.²² This theory posits that viral genomes can be thought of as comprising a series of functional modules, such as those containing the capsid and the polymerase, that can be exchanged through recombination, and in doing so sometimes create entirely new viruses. For example, it has been suggested that some RNA viruses were created through a process of modular evolution.⁸⁸ In addition, there is evidence that recombination may occasionally reflect aspects of genome modularity in some small DNA viruses,^{129,146} as well as some RNA viruses, which is compatible with a form of modular evolution. However, this pattern more likely reflects essentially random LGT across the viral genome with natural selection then filtering out those transfers that reduce fitness, which tend to occur at intragenic locations, rather than LGT occurring at specific genomic sites as specified in the original modular evolution model.¹⁷³ Similarly, although LGT is a common occurrence in dsDNA viruses, it is another thing to say that these transfer events involve distinct functional *modules*, rather than occasional genes, and there is as yet no good evidence that new DNA viruses have been created by LGT. In sum, the role of modular evolution in the generation of virus diversity remains uncertain.

BASIC DEFINITIONS AND METHODS

Epidemiology deals with the occurrence of diseases in populations. Historically, epidemics of viral disease were recognized long before their causal agents were discovered, and viral epidemiology was one of the first aspects of the science of virology to be developed. Evolving insights into the pathogenesis and molecular aspects of virology have provided an increasingly rational basis for understanding the epidemiology of viruses. In this chapter, the biology of viral infections is used to explain the essentials of viral epidemiology.

Incidence and Prevalence

The quantification of disease occurrence is the cardinal feature of epidemiology. To accomplish this, the concept of rates was introduced, and rates have become the basic coinage of epidemiology (Fig. 12.1). Rates are fractions in which the numerator is the number of cases of disease and the denominator is a measure of the population. The *incidence rate* (also called the *attack rate* for acute infectious diseases) is used to quantify the number of new infections. A population and a time frame are defined, and the number of new cases in that population during that interval of time is counted. Note that the denominator includes both the size of population and time frame, and is often expressed as person-years (or any other standard interval of time; e.g., “thousand person-years” or “hundred person-weeks”). The incidence rate is then expressed as “cases per thousand person-years” or a similar term. Also note that the time element may be omitted in expressing incidence; the reader must then determine by context the time frame used.

Prevalence, technically not a rate but a ratio, refers to the total number of cases present within a specified time interval. Thus, the numerator in prevalence includes not just new cases but cases carried forward from the period prior to the specified time interval. When point prevalence is computed, a particular narrow time frame is selected, and the population recorded for that time frame constitutes the denominator. All cases “prevalent” on that date constitute the numerator. Prevalence is expressed as a ratio such as “cases per million”; note that there is no time parameter in this ratio.

Changes in incidence and prevalence may be divergent. A control program for human immunodeficiency virus (HIV) infection, for example, could decrease HIV incidence within a population through effective preventative measures but increase the prevalence of HIV infection through access to antiretroviral therapy and improved survival.

In epidemiology, consistency is a virtue. When cases and populations are counted prior to computing rates, care must be

FIGURE 12.1. Computation of incidence rate and prevalence ratio.

The shaded area defines a population and a time frame that can be expressed as person-time units. Cases of disease are indicated by circles (placed according to the date of their onset) and arrows for duration of illness. Solid circles would be counted for computation of incidence, whereas open circles would be excluded because they had onset outside the designated time frame or were resident outside the population boundaries. Incidence equals the number of cases divided by population-time units. Prevalence would be determined by a single vertical line across the hatched area: Cases active at that time point would be divided by the size of the population to compute the prevalence.

taken to use the same definition for numerator and denominator. Persons counted in the denominator should be at risk to be a case in the numerator if infected. For instance, if incidence is computed for the population of Philadelphia for 2011, a case hospitalized in the city but resident outside the city would not be counted. A case with onset in December 2010 but still ill in 2011 would not be counted as an incident case but would be a prevalent case.

What distinguishes infectious disease epidemiology from chronic disease epidemiology is that the former accounts for *dependent happenings*, a term introduced by Ronald Ross,¹⁰² in which the incidence of a disease depends on its prevalence within a population.⁴⁵ Traditional epidemiologic and statistical methods that infer relationships between exposure and disease outcome assume that the outcome in one individual is independent of the outcome in other individuals, an assumption that is invalid for communicable viral infections.^{54,82}

Sources of Data

In practice, the accurate collection of data for the computation of rates is often a major undertaking, whereas the computations are relatively simple. Furthermore, the practicing epidemiologist must frequently work with incomplete and inaccurate information. In most developed countries, denominator (population) information is usually good, and numerator (case) information is the major problem. In resource-limited settings, accurate population data may be unavailable.

For infectious (viral) diseases, there are several sources of case data. Passive surveillance denotes the continuous reporting of disease by healthcare workers. By law, many viral diseases are

designated as “reportable,” and in theory, the reporting of all cases is required. Cases are reported by practicing physicians, hospitals, or laboratories to local health jurisdictions, which in turn relay reports to a central state office whence they are transmitted to a national center (e.g., the U.S. Centers for Disease Control and Prevention). The weakest link is the initial report; in practice, only a small fraction of cases of many common viral diseases (such as 10%–15% of measles or hepatitis B cases) are reported to the national center (called the *reporting efficiency*). However, if the proportion of cases reported is consistent between geographic locales and between years, these reports may be used to monitor trends. Consistency is an important caveat, because the proportion of cases reported may increase if the absolute number of cases decreases. Changes in the case definition also may result in spurious changes in surveillance data. Reporting of certain rare or serious diseases, such as poliomyelitis or acquired immunodeficiency syndrome (AIDS), is often close to 100%; in such instances, reported cases can be used with much greater confidence for calculation of rates. Within increasing interest in the pandemic spread of respiratory viruses and the emergence of new zoonotic viral pathogens, global disease surveillance networks have been established to provide data on disease incidence and transmission in real time,¹⁴ including the Program for Monitoring Emerging Diseases (ProMED) and the World Health Organization’s Global Outbreak Alert and Response Network (GOARN).

Active case detection through epidemic investigation is the traditional approach to collecting information on outbreaks of disease. Such investigations are usually initiated by public health authorities but may be instigated by healthcare workers or patient families. The investigation is tailored to the situation and to the resources at hand, although experience has set certain guidelines, particularly for recurring outbreaks such as food-borne diseases. The purpose of such studies is several: (a) to classify the illness and determine the causative organism, (b) to assess the extent of the outbreak and its economic and health impact, (c) to abort the outbreak or prevent recurrent episodes, and (d) to inform or reassure the public. The first recognition of a new disease or isolation of a previously unknown virus has been accomplished as a result of an epidemic investigation. Examples are the identification of Lassa virus; Marburg virus; Sin Nombre virus (SNV), a hantavirus that is the cause of acute pulmonary syndrome; severe acute respiratory syndrome (SARS)-coronavirus; and the 2009 H1N1 influenza virus.

Serological surveys may be used to detect the footprints that a virus leaves in a population. Serosurveys are particularly useful for viruses because most viral infections leave an imprint on all infected individuals—that is, the presence of immunoglobulin G (IgG) antibody, which often is life long. Because many viruses cause asymptomatic infections or nondescript illnesses in addition to diagnosable diseases, serological surveys identify inapparent as well as apparent infections. Incident viral infection can be identified using assays for immunoglobulin M (IgM) antibody or antibody avidity, whereas IgG antibodies indicate prior infection or vaccination.

Cohort and Case-Control Study Designs

Modern epidemiology has made one outstanding contribution to the discipline—namely, the extension of hypothesis testing from the laboratory to populations. In general, the epidemiologist

TABLE 12.1 Hypothetical Data to Illustrate Computations for a Cohort and a Case-Control Study of Vaccine Efficacy

Group	2012 Cases	Population	Rate per 100,000 person-years	Relative risk
Cohort study^a				
Vaccinated	100	1,000,000	10	0.33
Unvaccinated	900	3,000,000	30	
Group	Cases	Controls	Odds	Odds ratio
Case-control study^b				
Vaccinated	10	25	10/90	0.33
Unvaccinated	90	75	25/75	

Vaccine efficacy = $1 - \text{Relative risk} = 0.67$.

^aCohort study: Two populations, vaccinated and not vaccinated, are followed for 1 year, and cases occurring in each group are recorded. Rates are calculated, and the ratio of rates gives the relative risk for those who were vaccinated. In this instance, relative risk is lower for those with than without the attribute (immunization). The validity of this design depends on the assumption that vaccinated and not vaccinated groups would be at equal risk except for the attribute under study.

^bCase-control study: A group of 100 cases and 100 controls are randomly picked to be representative of the groups from which they are drawn. Subjects in each group are classified as vaccinated or not vaccinated, and two ratios are computed: vaccinated cases/vaccinated controls and unvaccinated cases/unvaccinated controls. The odds of a case being exposed (vaccinated) and the odds of the control being exposed are used to compute the odds ratio, which provides an estimate of the relative risk. The validity of the case-control design depends on two assumptions: (a) the case and control groups are representative of the larger groups from which they are drawn, and (b) the number of cases is very small ($<1/10$) relative to the total population.

attempts to test the hypothesis that one or more population variables influence the occurrence of a specified disease and, if so, to quantify this effect and estimate confidence limits. There are two general designs used for such studies: *cohort* and *case-control* studies. The essence of these designs is summarized next, and the reader is referred to appropriate texts for methodological exposition.³⁵

Cohort Studies

In a cohort study, which may be conducted prospectively or retrospectively, the population is divided into two groups, one with and one without a specified exposure or attribute. Both groups are followed prospectively for the *incidence* of the disease under study, and incidence rates for both groups are then computed. A hypothetical example is shown in Table 12.1. In this example, the population attribute is immunization against a specified viral disease, and the attack rate in the immunized population is one-third the rate in the unimmunized control group. The *relative risk* (RR) associated with immunization is 0.33, and vaccine efficacy is 67% [$(1 - \text{RR}) \times 100$]. There is one important assumption underlying the validity of such a study: The immunized and unimmunized groups are at equal risk of disease. For various reasons, this assumption may not be correct. Differences in the risk of disease between two study groups may be minimized by random allocation of the exposure (in this case, the vaccine) when that is deemed ethical. However, random allocation of exposure is not possible unless the study is of an intervention. Stratifying each study arm according to parameters such as age, race, and socioeconomic status and then comparing rates for each subgroup can be used to identify inequalities between the two groups. Table 12.2 summarizes one such study of polio vaccine and documents the problems of comparing groups (in this instance, vaccinated

and unvaccinated) that are not at equivalent risk of disease (in this instance, poliomyelitis).

More complex study designs are used to measure indirect effects of vaccines or other interventions that affect the transmission of viral pathogens. Such indirect effects include protection of non-vaccinated individuals through decreased transmission from vaccinated individuals, referred to as herd immunity.²⁷ Cluster randomized trials—for example, cohort studies in which communities rather than individuals are randomized to receive the intervention—allow direct measurement of the indirect effects of vaccines by comparing the risk of disease outcomes in nonvaccinated individuals residing in intervention and control communities.^{44,46}

Case-Control Studies

Cohort studies usually require extensive resources and time because they necessitate the enrollment of large numbers of subjects who must be followed for a period of months or years; the less frequent the expectation of disease, the larger the population or longer the follow-up needed. Needless to say, the costs of prospective cohort studies can be great, limiting them to situations such as the introduction of a new drug or vaccine, as illustrated in Table 12.2. Case-control studies can be more cost-effective because they involve smaller numbers of subjects and do not require longitudinal follow-up, particularly if the disease outcome is rare. Table 12.1 shows a simplified version of such a study. In this instance, 100 cases of the study disease and 100 unaffected control subjects are identified and classified according to the exposure or attribute (vaccination) under study. For both vaccinated and unvaccinated individuals, an odds ratio is computed. Because, under certain assumptions, the odds ratios have the same relationship as the rates computed in the prospective study shown in the upper half of Table 12.1,

TABLE 12.2 The 1954 Field Trial of Poliomyelitis Vaccine: Comparison of Attack Rates for Vaccinated and Unvaccinated Children^a

Study area	Vaccination group	Population	Paralytic cases	Rate per 100,000	Estimated efficacy
Placebo areas	Vaccinated	201,000	33	16	72%
	Placebo	201,000	115	57	
	Not inoculated	339,000	121	36	
Observed areas	Vaccinated	222,000	38	17	63%
	Controls	725,000	330	46	
	2nd grade, not inoculated	124,000	43	35	

^aVaccine was administered in the spring of 1954, and children were followed prospectively through the summer poliomyelitis season. Placebo areas were divided into volunteers who were vaccinated, volunteers who received placebo inoculations, and nonvolunteers (not inoculated). Observed areas were divided into second-grade volunteers (vaccinated), second-grade nonvolunteers (not inoculated), and first and third graders (controls).

From Francis T, Jr., Napier JA, Voight RB, et al. *Evaluation of the 1954 Field Trial of Poliomyelitis Vaccine. Final Report.* Ann Arbor: University of Michigan; 1957.

the relative risk can be estimated as the ratio of the two odds ($0.4/1.2 = 0.33$). Two assumptions underlie the validity of the case-control design and analysis, specifically the use of the odds ratio as an estimate of relative risk: The two samples (cases and controls) must be representative of the population from which they are drawn, and the incidence of disease must be low so that cases comprise less than 10% of the total population. Because case-control studies are particularly useful to study risk factors for rare diseases, the second assumption is usually correct. The main challenge in designing case-control studies is the choice of a valid and representative control group, a subject considered in depth in epidemiologic texts.³⁵

BASIC BIOLOGICAL CONCEPTS

Susceptibility and Immunity

Many acute viral infections confer lifelong immunity. Upon re-exposure after initial infection, there is often reinfection but with minimal virus replication and an anamnestic immune response. Such reinfections are usually covert and almost never severe, resulting in minimal or no shedding of infectious virus. For certain viruses, such as poliovirus or rhinovirus, immunity is type specific and confers little protection against exposure to a different serotype. These simple facts have profound implications for viral epidemiology. For epidemiologic purposes, a population may be divided into three groups: susceptible, infected (and infectious), and immune. Persons infected at any time in the past may be considered immune (recovered) and are exempt from disease and unable to act as links in a transmission chain, whereas susceptible individuals can be infected, become infectious, and experience disease. This compartmentalization of the population is the basis for simple SIR (susceptible, infectious, recovered) models of virus transmission⁴ that can explain the periodicity in incidence as the outcome of the buildup and decline of susceptible individuals.

Susceptibility may not be present immediately after birth. IgG antibodies are actively transported across the placenta, conferring protective immunity to neonates and young infants.

For such viral infections, individuals move from a protected state to a susceptible one in the first year of life. Immunity can then be conferred by vaccination or infection.

Persistent viral infections differ from acute infections because the infected individual may be capable of transmitting infection over many years and may develop disease at any time during virus persistence. In the instance of persistent viruses, the population may be divided into uninfected susceptibles and immune-but-infectious persons who carry serological markers of prior infection but who are still capable of acting as links in the chain of infection. Important examples are hepatitis B virus, HIV, and several herpesviruses (herpes simplex virus, varicella-zoster virus, and cytomegalovirus) that establish latent infection capable of reactivation.

Parameters That Determine Incidence

For acute viral infections, the following three parameters determine incidence: the proportion of the population susceptible, the proportion of the population that is infectious, and the rate of contact between susceptible and infectious individuals, with *contact* defined as an encounter sufficient for transmission. The proportion of infected persons who become ill—the case infection ratio—determines the proportion of infected persons detected through case surveillance.

Proportion Susceptible

When a population is exposed to an infectious individual with a specific virus, the susceptible part of the population will determine the spread of the agent and account for all new cases. The proportion susceptible will reflect the past history of infection with the specific virus in the population and the past history of immunization for vaccine-preventable viral infections.

Proportion Infectious

The proportion of susceptibles who become infected, and subsequently infectious, during a fixed period of time (e.g., year or season) can vary widely, depending on the dynamics of transmission, which is influenced by the density of susceptibles and contact patterns between susceptible and infectious individuals.

TABLE 12.3 Estimated Case Infection and Case Fatality Ratios for Selected Viral Infections

Virus	Cases per 100 infections	Fatalities per 100 cases	Comment
Smallpox	>95	<1	Variola minor
	>95	25	Variola major
Measles	>95	0.1	United States, 1970
	>95	2	Africa, 1988
Poliomyelitis	<1	5	United States, 1955
Hepatitis B	50	3	United States, adults
	<1	<0.1	Taiwan, infants

Rate of Contact Between Susceptible and Infectious Individuals

The rate of contact between susceptible and infectious individuals determines the dynamics of viral spread within a population. This rate depends on the mode of transmission (e.g., respiratory, oral–fecal, sexual, or vector-borne), age-specific contact patterns or networks between individuals, and the distribution of susceptible and infectious individuals within a population. Spatial clustering of susceptible individuals can result in outbreaks despite a high proportion of immune individuals within the population.

Case Infection and Fatality Ratios

The proportion of infections resulting in overt disease—the pathogenicity of the organism—is characteristic for each virus and is strikingly different for different agents. One of the most important contributions of modern laboratory methods to viral epidemiology was the identification of inapparent or subclinical infections and the insight that most infections caused by some viruses were asymptomatic. The relative frequency of subclinical infections is expressed as the *case infection ratio*—that is, the number of clinical cases per 100 infections. The lethality of disease is a different parameter that represents the virulence of the organism and is designated as the *case fatality ratio*. The case fatality ratio is the number of deaths attributable to an infection per 100 cases. Table 12.3 lists selected common viral infections and shows estimated case infection ratios and case fatality ratios for each. It is noteworthy that there is no regular relationship between the case infection ratio and severity of illness (i.e., between pathogenicity and virulence). For instance, measles has a very high case infection ratio (>95:100) but a low case fatality ratio in developed countries (<1:1000 in the United States). Conversely, poliomyelitis has a low case infection ratio (<1:100) but a higher case fatality ratio (~5:100). Determining the case infection ratio is an important objective of outbreak investigations of novel pathogens, such as severe acute respiratory syndrome (SARS)-coronavirus and the 2009 pandemic H1N1 influenza virus. Typically, early in an outbreak, only cases that come to clinical attention are counted as incident cases, resulting in an underestimate of the true incidence. Accurate measurement of subclinical infection requires population-based surveys with laboratory confirmation (e.g., serological surveys).

Incubation, Latent, and Infectious Periods

The course of infection in a single individual can be conveniently divided into several periods.²⁹ The interval from acquisition of infection to onset of illness is the *incubation period*. Note that “onset of illness” must be explicitly defined for each disease and is often measured by the first day on which pathognomonic signs or symptoms are reported. The interval from acquisition of infection to onset of infectiousness is the *latent period*. For most viral diseases, the latent period is shorter than the incubation period. Consequently, the infected individual begins to shed virus prior to the onset of illness (smallpox is a notable exception) and continues to shed during and sometimes after recovery from the acute illness. The effectiveness of quarantine measures is reduced when the latent period is significantly shorter than the incubation period as the infectious individual goes unrecognized. The period during which the infected person is potentially infectious for others is the *infectious period*.

Incubation periods for any viral disease vary around the mean, as illustrated in Figure 12.2. When a frequency distribution of individual incubation periods is plotted, it usually has a longer tail at the high end of the distribution (right skewed). If the frequency is plotted against the logarithm of time, the data often approximate a normal distribution.¹⁰⁴ This log-normal distribution is characteristic of the incubation periods of many viral infections.⁶⁰

Generation Time and Serial Interval

The average period between infection of an individual and transmission to others is the *generation time* or transmission interval. From studies of selected outbreaks, the average interval between onsets of successive waves of cases (called the *serial interval*) has been determined, and the generation time is often assumed to be equal to this interval as the best approximation available. This is because it is often impossible to know the exact time of infection. These relationships are shown in Figure 12.3 for a typical acute viral infection.

TRANSMISSION OF VIRUSES

There are two major patterns of transmission into which viruses may be classified: viruses maintained in a single species and viruses that alternately infect different host species. There

FIGURE 12.2. Log-normal distribution of incubation periods. **Upper panel:** Incubation period distribution is shown for poliomyelitis; there is a right-hand tail. **Lower panel:** The same incubation periods when plotted on a logarithmic scale. Logarithmic incubation period approximates a normal distribution, and the standard deviation may be computed (on the logarithmic scale). The dispersion factor (DF), a measure of the variation of incubation periods, is the antilogarithm of the standard deviation. The mean (m) is shown, together with the standard deviation (points a and b on the graph). The log DF equals the interval ($\log m$ to $\log a$) or the interval ($\log b$ to $\log m$). In this instance, m is about 10.3 days, a is 6.5 days, b is 16.25 days, and DF is 1.58—that is, about two-thirds of the incubation periods fall into the range $(1.58 \times \text{mean})$ to $(\text{mean}/1.58)$. are a few apparent exceptions, such as rabies and influenza viruses, which spread across species boundaries; however, even in these instances, cycles of transmission between different species may be self-contained. For agents that infect humans, a second distinction may be made between those viruses that rely on human transmission for their perpetuation (the majority)

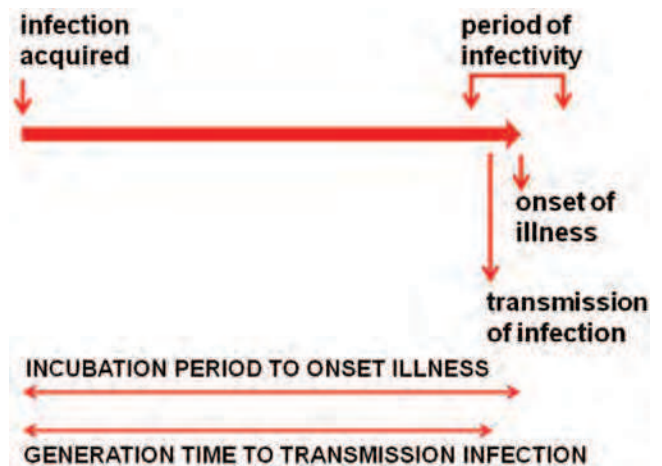

FIGURE 12.3. Incubation period and generation time. Incubation period is the interval between acquisition of infection and onset of illness, whereas generation time is the interval between acquisition of infection and transmission to another person. This diagram shows the mean for each parameter; in practice, there is a spread around this mean.

and those viruses maintained in an extrahuman cycle for which humans are a dead-end host. Examples of these patterns are set forth in Table 12.4.

Viruses Maintained Within a Single Host Population

Each virus has characteristic modes of host-to-host transmission: (a) direct person-to-person transmission through respiratory, fecal–oral, sexual, blood, or from mother to child, or (b) indirect transmission through fomites or vectors. Viruses that cause acute short-term infections require efficient transmission to subsequent hosts. Such infections are characterized by a relatively short infectious period and the excretion of high titers of infectious agent over a limited period of time, as in the instance of influenza, measles, and smallpox viruses. Viruses that cause persistent infections do not require such highly efficient modes of transmission, because they are excreted continuously or intermittently for many years and thus have a long infectious period to maintain virus

TABLE 12.4 Major Transmission Patterns of Viral Infections of Humans

Transmission pattern	Maintenance cycle	Example
Human to human	Human to human	Measles virus Hepatitis A virus Human immunodeficiency virus
Animal to human	Animal to animal	Rabies virus Hantavirus
Vector to human	Vector to human	Dengue virus Urban yellow fever virus
Vector to human	Vector to vertebrate	St. Louis encephalitis virus Western encephalitis virus

TABLE 12.5 Transmission Mechanisms of Human Viruses Maintained by the Person-to-Person Route

General category	Transmission mechanism	Example
Horizontal	Respiratory	Influenza virus
	Fecal–oral	Rotavirus
Vertical	Placental–fetal	Rubella virus
	Maternal parturition	Herpes simplex virus
		Human immunodeficiency virus
	Maternal breast milk	Human immunodeficiency virus
	Germ line	Unknown

transmission. Horizontal transmission is often used to designate these modes of transmission from person to person.

Vertical transmission is used to denote transmission between parent and offspring. Such transmission may occur during gestation, by passage of virus across the placenta (e.g., rubella virus and HIV); perinatally during birth (e.g., herpes simplex or hepatitis B viruses); or from the mother via colostrum or milk (e.g., HIV). Germline transmission, another mode of vertical spread, is seen with certain animal retroviruses such as murine leukemia virus, which are transmitted as an integrated provirus that may be transcribed into infectious virus. Although retroviral sequences are carried in the human genome, there are presently no proven instances where these have been shown to function as infectious virions. Selected examples of horizontal and vertical transmission are listed in Table 12.5.

Viruses That Alternately Infect Different Host Species

Arthropod-borne viruses (arboviruses) are usually maintained by continuously cycling between an insect host and a vertebrate host. In most instances, the virus replicates optimally in a single species or in a few closely related species of insects, which constitute the major, if not exclusive, vectors. Because most blood-feeding insects have a clear feeding preference for a few vertebrate species, this determines and limits the vertebrate species involved in the maintenance cycle. For some arboviruses, alternate maintenance cycles are limited to the insect host, with transovarial or sexual transmission from generation to generation of insects. These insect cycles may be critical to perpetuation of the virus during adverse conditions, such as overwintering, but otherwise play a minor role in viral dissemination.

There are only two arboviruses—dengue and urban yellow fever—of which humans are the major vertebrate host. In other instances, such as St. Louis encephalitis and La Crosse encephalitis, humans are accidentally infected when the vector mosquito happens to feed on humans as an alternate to the preferred vertebrate blood source, such as birds or woodland rodents.

Terminal Hosts

A *dead end* or *terminal host* is one not involved in maintaining viral transmission. Humans are occasional terminal hosts for

several viruses maintained in extrahuman cycles. These include arbovirus infections, with the exceptions of dengue and yellow fever viruses noted earlier. In addition, there are several zoonotic infections, most notably rabies, in which humans are terminal hosts. Transmission of rabies is often by bite, although for most other terminal infections in this group (such as Korean and Bolivian hemorrhagic fever viruses), environmental exposure to fomites is responsible. Table 12.4 lists examples of viral infections in which humans are terminal hosts.

Transmission of Persistent Viral Infections

The transmission of persistent viral infections differs from that of classic acute infections. Those persistent infections that can become latent, such as the herpesviruses, are transmissible intermittently during periods of activation. Thus, one individual may be infected in childhood and transmit infection 50 years later during a recrudescence. The ability for a single link in the infection chain to extend over such an interval has important implications for perpetuation and eradication of infection. Infections such as those caused by hepatitis B virus and HIV, which are transmissible over many years, are often transmitted very inefficiently. Thus, hepatitis B is transmitted to susceptible household contacts at a frequency of less than 1 per 100 person-years exposure, and HIV is transmitted to sexual contacts at a rate of approximately 1 transmission per 100 to 1,000 contact episodes, with the risk of transmission directly correlated with HIV viral load.³⁶ For such infections, transmission requires passage of body fluids or of viable infected cells. Despite inefficient transmission, the number of new infections initiated by each persistent infection may be high because of the long infectious period. An epidemic curve caused by such a virus may stretch over years rather than weeks, and the mathematical modeling of such persistent viral infections is profoundly different from acute infections because infectious individuals are not rapidly converted to noninfectious immunes but continue to accumulate.⁸

Quantitation of Transmission and the Basic Reproductive Rate

The transmissibility of viral infections may be quantified by the basic reproductive rate (R_0), defined as the average number of new infections initiated by a single infectious individual in a completely susceptible population over the course of that individual's infectious period.⁴⁸ The reproductive rate of a pathogen is a function of pathogen characteristics as well as contact patterns within the community. Examples of R_0 are 12 to 18 for measles virus, 5 to 7 for poliovirus and smallpox virus, and 1.5 to 2.0 for influenza viruses.⁴

R_0 is determined by (a) the number of contacts between an infected individual and others, (b) the proportion of these contacts that are susceptible (assumed 100%), and (c) the probability of transmission per susceptible contact. The effective or net reproductive number (R) is the actual average number of secondary cases that occur and equals the product of R_0 and the proportion of susceptible individuals in the population. R is smaller than R_0 because not all individuals in real populations are susceptible, because of either prior infection or immunization. When R is greater than 1, the incidence of infection increases; when R is less than 1, the incidence wanes. When R equals 1, the number of infections is constant. Control programs aim to reduce R to below 1 to achieve disease elimination.

A simple mathematical expression that captures the three parameters for a directly transmitted pathogen is $R = \beta XD$, where β represents the transmission coefficient (a measure of the rate of contact between individuals and the likelihood of transmission during that contact per unit time), X is the proportion of susceptible individuals, and D is the duration of infectiousness. As can be seen from this simple formulation, elimination of a viral infection could be achieved by reducing effective contacts (e.g., quarantine), reducing the proportion of susceptible individuals (e.g., through vaccination), or reducing the infectious period (e.g., treatment to reduce viral load).

Modeling Viral Dynamics

Mathematical models of viral dynamics with varying degrees of sophistication are widely used by infectious disease epidemiologists to understand temporal and spatial patterns of virus transmission within populations and to evaluate the potential impact of control strategies. Mathematical models help to quantify our understanding of infectious disease dynamics and can be used to assess interventions for which epidemiologic studies are not feasible or ethical (e.g., strategies to contain a smallpox outbreak as a result of bioterrorism).⁵⁴ The use of mathematical models in infectious disease epidemiology has a long history, with one of the earliest successful approaches being the model of malaria transmission dynamics developed by Sir Ronald Ross in the early 20th century.¹⁰³ Subsequent models of infectious disease dynamics were developed by Wade Hampton Frost and Lowell Reed (the Reed-Frost model), in which the incidence of newly infected persons was based on the probability of contact between susceptible and infectious hosts.² The models developed by W. O. Kermack and A. G. McKendrick were the first to divide the population into the three classes of individuals discussed earlier (susceptibles, infectious, and recovered; hence, SIR models) and estimated the number of new infections as a function of the number of susceptible and infectious individuals.⁵² These deterministic, compartmental models (based on difference or differential equations depending on whether time is treated as a discrete or continuous variable) were expanded and popularized by Roy Anderson and Robert May⁴ and became the basis for much infectious disease modeling. Variations on the basic SIR model include the addition of other compartments or classes of individuals (e.g., infected but not infectious or a period of maternally acquired protection), age-specific contact patterns, and stochastic processes. Useful models balance the goals of realism and simplicity, as more complex models require a greater number of underlying assumptions and parameter estimates. Useful models clarify our conceptual framework of viral transmission dynamics, suggest which variables are most important for transmission and require careful measurement, and generate new hypotheses. In addition, models can be used to estimate the likely size of an epidemic, its time course and periodicity, the reproductive number R , and the expected impact of various interventions. Finally, model validation against epidemiologic data is a critical component of model building and use.

Measles has long been a favored disease by infectious disease modelers because of the simple transmission dynamics and the long time series available as a result of the readily distinguishable clinical characteristics. Mathematical models of measles virus transmission allow for exploration of the impact of various vaccination strategies, including the optimum age

at measles vaccination and the use of mass vaccination campaigns,^{59,74} that would otherwise be difficult to evaluate in epidemiologic studies. Model results suggest that the best age at which to vaccinate against measles depends critically on the age distribution of cases of infection prior to the introduction of control measures,⁷⁴ the introduction of mass vaccination will induce a temporary phase of low incidence of infection before the system settles to a new pattern of recurrent epidemics,⁷⁴ and that frequent, relatively low coverage mass vaccination campaigns are effective in reducing measles virus transmission.⁵⁹

DESCRIPTIVE EPIDEMIOLOGY

A hallowed maxim in epidemiology is that a complete description of epidemic or endemic disease must include the parameters person, place, and time. The collection and display of this descriptive information is a necessary first step in understanding the epidemiologic mechanisms leading to occurrence, distribution, and course of an epidemic. This simple, systematic approach is a surprisingly powerful tool in analysis. A few selected examples are presented in this section to demonstrate the application of descriptive epidemiology to the understanding of virus transmission.

Person

In tabulating cases of viral infection, the epidemiologist looks for features that distinguish affected persons from the general population to identify risk factors for infection and disease. Clues may exist in demographic features and behavioral characteristics, such as age, sex, race, occupation, residence, or any aspect of personal conduct. Such variables are frequently the most important initial step in understanding an outbreak.

The first recognized outbreak of St. Louis encephalitis in 1933 involved a classical exercise in “shoe leather” epidemiology,⁶⁹ the finding of which led to the proposal that the disease was transmitted by an arthropod vector rather than by person-to-person contact. When this outbreak occurred, neither the disease nor the causal agent was known. Because it was an acute neurological disease, occurring in the summer, it was first thought to be a form of poliomyelitis or to be transmitted in the same manner through the fecal–oral route. The characteristic encephalitic manifestations made it relatively easy to identify many of the cases clinically. When these cases were assembled, and rates estimated, it became apparent that the incidence was greater in the suburbs of St. Louis than in the city proper. Furthermore, there was a striking concentration of cases among the inhabitants of one institution located in the suburbs; however, a comparison of several adjacent institutions revealed even more dramatic discrepancies, illustrated in Table 12.6. First, there were no cases in the personnel in an infectious disease hospital caring for many acute encephalitis cases—strong evidence against person-to-person transmission. Second, there were high rates in an almshouse but very low rates in two insane asylums. Investigation revealed that the almshouse lacked screens, whereas the other three institutions were screened. These observations were strongly reminiscent of the classic findings of the Reed commission investigating yellow fever in Havana⁹⁸ and suggested mosquito transmission. Finally, it was observed that the suburbs of St. Louis, although home to many affluent residents, lacked the system of storm

TABLE 12.6 Attack Rates for St. Louis Encephalitis in Four Institutions in the Suburbs of St. Louis During the Epidemic of 1933^a

Institution	Population	Cases	Rate per 100,000
Mental hospital	400	0	—
Hospital for the insane	4,000	0	—
Isolation hospital	500	0	—
Almshouse (infirmary)	1,200	13	10,800

^aOf these four institutions, three had adequate screening, whereas one (infirmary) did not. The isolation hospital cared for 300 patients with St. Louis encephalitis, but no cases occurred among the staff, estimated at 500.

From Lumsden LL. St. Louis encephalitis in 1933: observations on epidemiological features. *Public Health Rep* 1958;73:340–353.

sewers present in the city. More sites with standing ground-water existed in the suburbs, and in the hot, dry summer of 1933, these sites were prime mosquito breeding sites. These observations suggested the mechanisms of transmission to the investigating epidemiologists.

The “Cutter incident” offers another example where descriptive epidemiology defined an unusual distribution of disease in a population, leading directly to the cause.⁸⁶ In mid-April 1955, newly approved inactivated poliomyelitis vaccine was distributed throughout the United States for immunization of children 5 to 9 years of age—the age group considered the highest risk and therefore given preference in the utilization of limited vaccine supplies. About 2 weeks later, at the end of April, reports were received of cases of acute paralytic poliomyelitis occurring in a small number of recently immunized children. Because this was close to the seasonal trough in poliomyelitis incidence, relatively few cases of poliomyelitis were occurring in the general population, thus a small number of vaccine-associated cases were particularly striking. Furthermore, vaccine-associated cases were confined to a few of the western states. It quickly became apparent that this geographic distribution was related to the manufacturer of vaccine. Vaccine had been produced by five manufacturers, and most cases were

associated with vaccine produced by Cutter Laboratories, which produced the vaccine mainly used in western states. When rates were tabulated for different production pools of Cutter vaccine, the association focused on two high rate pools, as indicated in Table 12.7. Subsequent investigations showed that there were inadequacies in the inactivation and safety testing protocols recommended by the government, permitting the release of vaccine lots containing residual infectious virulent virus.

Age Distribution

The age distribution of viral infection reflects differences in risk. For many endemic human viruses, the cumulative incidence of infection reaches 100% of the population. In such instances, disease is confined to children or to children and young adults, because older individuals are immune as a result of prior subclinical or apparent infection. Poliomyelitis prior to the introduction of vaccine is such an example, and differences in age distribution of disease in different regions or in the same population in different eras reflect differing transmission rates.⁸⁷ Where this enterovirus is transmitted readily, cases are confined to young children; contrariwise, in countries with more rigorous personal hygiene, infection may be delayed so that poliomyelitis occurs up to age 30 or older.⁸⁴ Figure 12.4 compares these age distributions and shows the parallelism with the acquisition of immunity.

For viruses that never infect more than a small proportion of a population, the age distribution of cases reflects differences in exposure or case infection ratio rather than immunity. An example is St. Louis encephalitis, which produces unpredictable outbreaks in different areas of the central United States and is infrequent enough so that most of all age groups are susceptible. Attack rates are typically lower in children and higher in the elderly (10-fold differences). A classic investigation of an epidemic in Houston, Texas, showed that, surprisingly, the frequency of infection was very similar for all ages, indicating that age-specific differences in the case infection ratio accounted for age-specific clinical attack rates.⁹⁵

Age-specific differences in case infection ratios can be a key determinant of epidemiologic patterns of disease. In some instances, infants experience much more severe disease than do adults. A classical example is the outbreak of measles that

TABLE 12.7 The Cutter Incident: Attack Rates Among Children Receiving Cutter Vaccine According to Production Pool, United States, Spring 1955^a

Production pool	Number of inoculations	Paralytic poliomyelitis cases	Rates per 100,000
468	73,700	34	46.1
746	48,000	17	35.4

FIGURE 12.4. Age distribution of poliomyelitis cases and immunity.

A comparison of cumulative distribution of cases of poliomyelitis and prevalence of antibodies to type 2 poliovirus in two populations, Cairo and Miami, to show that the age distribution of cases reflects the ages at which infection is acquired. There are few cases above age 3 years in Cairo and above age 30 years in Miami—the ages at which cumulative infection prevalence reaches 100%. (Data from Paul JR. Epidemiology of poliomyelitis. In: *Poliomyelitis*. Geneva: World Health Organization; 1955:9.)

occurred in the Faroe Islands in 1846.⁹³ Because measles had not occurred in this isolated site for more than 50 years, women of childbearing age were seronegative, and their infants lacked maternal antibody. During the epidemic, the case fatality ratio was about 20% in infants and below 1% in children and young adults (Table 12.8). This episode illustrates the biological role of passively acquired maternal antibody. On the other hand, hepatitis B virus causes inapparent but persistent infection in infants but acute liver disease followed by immunity in adults. In developing countries, infections are frequently transmitted from persistently infected mothers to their newborns, whereas

infection in developed countries is mainly transmitted to older children and adults. These differences account for the paradox that the attack rates for hepatitis B are higher in developed countries, whereas cumulative infection rates are much higher and the virus carrier state is more frequent in developing countries, as illustrated in Table 12.9.

Networks

In addition to identifying individual characteristics associated with viral infection or disease, epidemiologists increasingly are interested in transmission networks critical to the dynamics of viral infections within populations.⁶⁸ Network theory and analysis is a complex subject with a long history in mathematics and sociology but has recently been developed by infectious disease epidemiologists, in part because of the ability to characterize complex social networks, such as large-scale social and sexual networks.⁶² The epidemiologic study of social networks is facilitated by unique sampling strategies, including snowball sampling or respondent-driven sampling in which study participants are asked to recruit additional participants among their social contacts. For example, concurrent partnerships (as opposed to serial monogamy) can amplify the spread of HIV and other sexually transmitted infections.⁷⁸ Social networks were shown to affect transmission of 2009 H1N1 influenza virus and were responsible for cyclical patterns of transmission between the school, community, and household.¹⁵

Place

Historically, mapping the distribution of disease preceded the development of epidemiology and became more significant with the introduction of place-specific rates. A famous example is John Snow's mapping of cholera cases during the Broad Street outbreak in London. Mapping spatial patterns of disease distribution remains one of the most powerful and intriguing aspects of descriptive epidemiology and has been enhanced by remote sensing technologies¹⁰¹ and sophisticated spatial analysis tools, including patch and network models.¹⁰⁰

TABLE 12.8 Age-Specific Mortality Rates on the Faroe Islands During the Measles Epidemic of 1846 Compared to Years 1835–1845^a

Age group (Years)	Annual mortality per 100		
	1835–1845	1846	Excess in 1846
<1	10.8	30.0	19.2
1–9	0.5	0.5	—
10–19	0.5	0.4	—
20–29	0.5	0.7	0.2
30–39	0.8	2.1	1.3
40–49	1.1	2.7	1.6
50–59	0.9	4.4	3.5
60–69	2.0	7.7	5.7
70–79	6.5	13.1	6.6
80–100	16.8	26.0	9.2

^aThe mortality for 1846 is for January through August, the period of the epidemic. The excess mortality provides a crude estimate of measles-specific mortality during the epidemic. At least 80% of the population had measles during the epidemic, which was the first to occur since 1781.

Two outbreaks of St. Louis encephalitis in two cities of Texas illustrate the complexities of geographic epidemiology. A large outbreak in Houston in 1964 was concentrated in the center of the city with decreasing rates toward the outskirts (Table 12.10). Subsequent serological surveys showed that infection rates paralleled cases and also showed that high rates were associated with the lowest economic strata, open foundations, unscreened windows, and lack of air-conditioning, as well as with areas of standing water close to the banks of the river that flowed through center city. Conversely, in Corpus Christi, attack rates were highest in the suburbs, as shown in Table 12.11. In Corpus Christi, the determining factor was mosquito breeding in pools of standing water associated with lack of a storm sewer system rather than with reduced protection from mosquito attack.

Spatial Patterns and Traveling Waves

Spatial patterns of viral infections are not static but display complex dynamics,¹⁰⁰ one of which is traveling waves of transmission. Measles virus transmission was shown to exhibit spatiotemporal traveling wave patterns in England and Wales,

with regional movement from large cities to small towns.³⁹ The incidence of dengue hemorrhagic fever, a mosquito-borne disease caused by dengue virus, in Thailand was characterized by a spatiotemporal traveling wave emanating from the capital Bangkok.¹⁸ The spatiotemporal dynamics of rotavirus infection in the United States prior to the introduction of rotavirus vaccine, which typically started in the Southwest in late fall and ended in the Northeast 3 months later, was explained by spatiotemporal variation in birth rates and thus the introduction of susceptible hosts.⁹⁶

Time

Seasonality

Many acute viral infections exhibit striking seasonal patterns in incidence.³⁰ In temperate climates, some viral infections peak in the winter, whereas others peak in the summer. In general, respiratory infections spread more readily in the winter, although they may peak at different times. Conversely, the incidence of enteroviral infections peak in the summer, although rotaviruses are a striking exception, as noted earlier. Arbovirus infections are confined to the summer months, when their vectors are active.

TABLE 12.10 Regional and Socioeconomic Differences in Attack Rates (per 100,000) for St. Louis Encephalitis, Houston, Texas, 1964^a

Circle	White upper class	White middle class	White lower class	Nonwhite	Totals
1 (innermost)	—	70	102	77	77
2	34	73	51	50	50
3	14	20	30	20	20
4	2	10	6	7	7
5 (outermost)	3	8	—	6	6

^aThe city was divided into concentric circles and into socioeconomically and racially stratified census tracts within each circle prior to computation of rates.

In the tropics, seasonal patterns of viral infections differ from patterns in temperate climates. Influenza virus transmission in the tropics can be either seasonal or relatively constant throughout the year.¹¹⁸ Strong seasonal transmission of measles virus in sub-Saharan Africa generates large, irregular measles outbreaks and is an example of nonlinear, chaotic viral dynamics.²⁶

The underlying explanations for seasonal differences remain elusive. In general, three types of mechanisms have been hypothesized to explain the seasonality of viral infections.⁶⁴ First are seasonal cycles in host resistance to infection, including seasonal differences in vitamin D levels.²² The second involves changes in host behavior and contact patterns, particularly the role of schools as shown for measles virus.²⁸ Third is the role of climatic factors, particularly temperature and humidity. An example is the seasonality of poliomyelitis in the northeastern United States, which contrasts with the

relative absence of seasonality for poliomyelitis in islands of Hawaii, where humidity remains relatively constant throughout the year (Fig. 12.5). This observation led to the hypothesis that viruses differ in their sensitivity to humidity,¹²⁰ with, for example, poliovirus rapidly inactivated during winter months of low humidity,⁸⁷ whereas influenza virus remains viable under similar conditions.¹³² More recently, influenza virus transmission was shown to decrease as vapor pressure (a measure of absolute moisture in air) increases, likely mediated by increased virus survival at low levels of vapor pressure.^{110,111}

The Impact of Viral Pandemics on Secular Trends in Life Expectancy

On rare occasions, the emergence of a new virus may initiate a pandemic so severe that it reduces the life expectancy of the human population. Although exceptional, such events deserve

FIGURE 12.5. Seasonal distribution of poliomyelitis in New England and Hawaii, and the seasonal variation in relative humidity. **Upper panel:** Cases for 1942–1951 for New England. **Lower panel:** Cases for 1938–1952 for Hawaii. (Data from Enright JR. Epidemiology of poliomyelitis. *Hawaii Med J* 1954;13:350–354; Nathanson N, Martin JR. FIGURE 12.6. The drastic effect of the acquired immunodeficiency syndrome pandemic on life expectancy in Botswana, compared with Japan and India. Life expectancy is computed from the age-specific mortality rates for each calendar year, which are averaged to obtain the expectancy for that calendar year. (Data from McMichael AJ, McKee M, Shkolnikov V, et al. Mortality trends and setbacks: global convergence or divergence? *Lancet* 2004;63:1155–1159.)

mention because of their enormous impact. The global influenza pandemic of 1918 was such an event.⁹² A type A influenza virus with an H1N1 genotype emerged, likely a recombinant between an avian and a human influenza virus. Because the human population under age 25 years was negative for H1 antibodies, this virus spread rapidly around the world and is estimated to have caused an excess mortality of about 40 million deaths in less than 1 year, sufficient to cause a transient reduction in life expectancy of about 15 years. Viral archaeology led to reconstruction of the genetic sequence of this virus and the generation of infectious virus through reverse genetics¹²⁵; however, its apparent high virulence has yet to be fully explained in molecular terms.¹²¹ A second striking instance is the impact of HIV/AIDS on life expectancy in some countries of sub-Saharan Africa (Fig. 12.6). In Botswana, for instance, AIDS reduced life expectancy by about 20 years, from age 63 to age 42—an effect whose magnitude has not been seen in recorded medical history.⁷⁵

VIRAL EMERGENCE

One of the most dramatic aspects of historical epidemiology is the appearance of a new viral disease. This may reflect (a) the true appearance of a new virus in the population, a rare but real possibility; (b) an increase in the case infection ratio so that an endemic infection is associated with a marked increase in disease incidence; or lastly, (c) the recognition of an existing but previously unidentified disease that can now be clearly diagnosed owing to new laboratory tests accompanied by heightened practitioner awareness.

Emergence of Novel Viruses

AIDS and other diseases associated with HIV are an only too familiar example of the emergence of a virus new to the population. AIDS first appeared in the United States and Europe

around 1979, and serological studies demonstrated that infection first occurred in the gay population of San Francisco 1 to 2 years prior to the recognition of the disease. The emergence of AIDS was re-enacted in India and Southeast Asia in the mid-1980s, when newly developed serologic and virologic methods permitted the infection to be followed from its earliest entry into the population. Evidence suggests that HIV-2 was derived from viruses indigenous to sooty mangabeys¹¹² and that HIV-1 originated in simian immunodeficiency virus (SIV) strains circulating in chimpanzees.¹¹³

Bovine spongiform encephalopathy (BSE) was first detected in the United Kingdom in the mid-1980s and was quickly identified as a spongiform encephalopathy similar to scrapie, an endemic disease of sheep. Detailed epidemiologic investigation strongly suggested that BSE represented a common source epidemic owing to the contamination of meat and bone meal nutritional supplements routinely fed to dairy cattle.⁹⁹ Scrapie-infected sheep tissues were included in the raw material used to produce the feed supplement, and a change (introduced in the late 1970s) in the production methods permitted scrapie infectivity to survive the production process at a residual level. The rapidly evolving epidemic (Fig. 12.7) led to the exclusion of ruminant tissues from feed supplements, a step that was predicted to terminate the epidemic. However, the long incubation period (averaging about 5 years with a range of 3–9 years) of BSE indicated that the epidemic would continue to evolve. The relatively long tail to the declining epidemic reflected a delay in implementation of the feed ban and a low level of direct cow-to-cow transmission, similar to that observed in scrapie of sheep.

In April 2009, a novel influenza A virus was identified from two children with respiratory symptoms in southern California as a consequence of field epidemiologic investigations.¹¹⁶ Within the first few weeks of identification, field and epidemiologic studies lead to the initial genetic characterization of the virus,³⁴ a description of the clinical and epidemiologic features of infected persons,²⁰ characterization of viral transmission (including the serial interval) within different populations, and assessments of population susceptibility through serological surveys.⁴⁷

FIGURE 12.7. The course of the epidemic of bovine spongiform encephalopathy (BSE) in Great Britain, with confirmed cases by year of report. (Data from Department of Environment, Food and Rural Affairs. *BSE: Statistics*. 2011, available at <http://archive.defra.gov.uk/foodfarm/farmanimal/diseases/atoz/bse/>)

FIGURE 12.8. The appearance of epidemic poliomyelitis in the United States from 1885 to 1916. The graph is based on reported cases (mainly paralytic) during an era when reporting was estimated at about 50%. (Data from Lavinder CH, Freeman SW, Frost WH. Epidemiologic studies of poliomyelitis in New York City and the northeastern United States during the year 1916. *USPHS Hyg Lab Bull* 1918;91:1–150; and Nathanson N, Martin JR. The epidemiology of poliomyelitis: enigmas surrounding its appearance, epidemicity, and disappearance. *Am J Epidemiol* 1979;110:672–692.)

Increase in the Case Infection Ratio

The dramatic appearance of epidemic poliomyelitis (then known as *infantile paralysis*) in Europe and the United States in the 19th century is illustrated in Figure 12.8.⁸⁷ In retrospect, it is clear that polioviruses had been endemic for millennia but that cases of paralysis were few and sporadic. The likely explanation is that an improvement in standards of personal hygiene reduced the transmission of this enterovirus, delaying infection of young children beyond the age during which they were protected by maternal antibody (see Fig. 12.4), and resulting in the first epidemics of infantile paralysis.⁹⁰ Support for this view was the re-enactment of the appearance of poliomyelitis in other countries (in the Middle East and Africa) during the 20th century. In such instances, it was possible to conduct serological studies that demonstrated the high prevalence of antibodies prior to the appearance of clinical epidemics. Furthermore, the secular trend continued in the United States,

with a gradual stepwise increase in the age distribution of paralytic poliomyelitis (Table 12.12) so that by the time of vaccine introduction in 1955, the term *infantile paralysis* had become outmoded.

New Recognition of an Existing Virus

La Crosse virus is a mosquito-transmitted bunyavirus that causes La Crosse encephalitis. The causal agent was first isolated from a fatal case in 1964¹²³ and led to the ability to distinguish this disease from the rubric of “arbovirus encephalitis, etiology unknown.” Beginning in 1964, about 100 cases have been reported annually, mainly from the midwestern United States. It is likely that the “emergence” of this disease reflected the ability to make the specific diagnosis, because the incidence did not change and serological studies indicate that infections were occurring at a similar frequency long before isolation of the virus was reported in 1965.⁴¹

A striking acute pulmonary syndrome with high mortality was first reported in the southwestern United States in 1993, and combined epidemiologic and laboratory investigation indicated that the agent, SNV, was a previously unknown bunyavirus belonging to the *Hantavirus* genus.⁸⁸ SNV is an indigenous virus of deer mice (*Peromyscus maniculatus*), in which it causes a persistent infection accompanied by virus excretion leading to production of virus-infected aerosols and exposure of humans. The emergence of SNV was the result of the recognition of a long-existing agent and disease that was brought to attention because of an unusual cluster of cases associated with a transient increase in the deer mouse population.

Possible Increased Frequency of Viral Disease Emergence

New viral diseases may be emerging as zoonoses at an increasing frequency.¹²⁹ Several secular trends have enhanced the probability of emergence of new viral diseases¹²⁷ (Fig. 12.9). First, the population of the world has inexorably continued to increase, and urbanization has concentrated a higher proportion of people in densely populated areas, facilitating the transmission of any new infection. Second, modern transportation permits the carriage of infections around the globe within a single incubation period. Third, man-made perturbations of the environment are occurring at an increasing pace, thus increasing the likelihood of transmission of zoonotic and arboviral infections

TABLE 12.12 Age Distribution of Poliomyelitis in Massachusetts, 1912–1952^a

Years	Age 0–4 years (%)	Age 5–9 years (%)	Age ≥10 years (%)
1912–1916	70	18	12
1920–1924	48	24	28
1925–1929	40	30	30
1930–1934	28	38	34
1935–1939	28	28	44
1940–1944	22	28	50
1948–1952	18	27	55

^aIncludes paralytic and nonparalytic cases.

FIGURE 12.9. Since the middle of the 19th century, many global changes have enhanced the probability of the emergence of new viral diseases of humans and animals. This chart depicts three examples of such trends. The rise in the human population has been accompanied by a massive increase in large urban populations, markedly increasing the risk of epidemic spread of infection. Dramatic reductions in the time to travel over long distances have increased the possibility of global transport of infectious agents over short periods of time. The number of large dams (dams >75 meters high built in the United States from 1890 to 1975) exemplifies increases in man-made manipulation of the environment. (Data from Anonymous. *Atlas of World Population History*. New York: Penguin Books and Allen Lane; 1978; Anonymous. *Statistical Yearbook, 38th Issue, 1990/1991*. New York: United Nations Publications; 1993; and Mandzhavidze NF, Mamradze GP. *The High Dams of the World*. Springfield, VA: Academy of the Sciences of the Georgian SSR and Clearinghouse for Federal Scientific and Technical Information; 1994.)

to humans. Finally, advances in fundamental virology have made available a new armamentarium of methods for the detection of previously unknown pathogenic viruses, although numerous challenges are raised by these methods in establishing causal relationships between pathogens and disease.⁶³ The current controversy over the potential association between xenotropic murine leukemia virus-related virus (XMRV) and chronic fatigue syndrome represents an example where the initial report of a causal association between a pathogen and disease based on molecular methods was not confirmed in subsequent studies.^{3,65}

An example that illustrates these forces is the emergence of West Nile virus (WNV) in the United States.⁵⁵ WNV, a mosquito-transmitted flavivirus, was endemic in northern and eastern Africa, the Middle East, and eastern Europe. However, WNV had been limited to these contiguous geographic areas, which is characteristic of the regional distribution of most arboviruses, in contrast to the global distribution of viruses endemic to humans. In 1999, an outbreak of arboviral encephalitis occurred in and around New York City, which was first thought to be caused by St. Louis virus, a flavivirus endemic to the United States. Further study showed that the outbreak was caused by WNV, which had never been found in North America. Although speculative, it appears that WNV was imported from the Middle East, likely by infected mosquitoes that were unpaid passengers on an incoming airliner. Because of the presence of vector mosquitoes permissive for WNV and susceptible avian hosts, WNV spread rapidly and is now endemic across the United States.⁸¹

EPIDEMICS

No medical phenomenon is more dramatic than the occurrence of an epidemic. The immediate cause of any viral epidemic is heightened transmission of the causal agent. Epidemics can be classified according to their principal mode of transmission as either common source or propagated.

Common Source Epidemics

Common source outbreaks are, as the term implies, owing to exposure to the virus from a common source, usually either in food, water, aerosol, or injected product. Common source outbreaks have the potential to be explosive because of the simultaneous exposure of many individuals; however, because the exposure is frequently limited in time, such outbreaks may be of relatively short duration. Finally, common source outbreaks challenge the epidemiologist, because unraveling the source may lead to termination of an ongoing outbreak or prevention of recurrences.

Two examples illustrate common source epidemics. At the beginning of World War II, the military decided to immunize a large number of troops against yellow fever because it was clear that there would be action in several tropical theaters where jungle yellow fever might be encountered. The attenuated 17D strain of yellow fever virus was a newly developed vaccine considered to be a safe and effective immunogen. Because vaccine efficacy depended on the infectivity of 17D virus, its stability was enhanced by including serum in the final formulation. Human serum was used (to avoid serum sickness), and almost 1,000 donors were recruited, most of whom were medical students at Johns Hopkins University. Unfortunately, at least one individual was a carrier of hepatitis B virus. As a result, over 400,000 troops received contaminated vaccine, causing a massive epidemic of hepatitis B infection (about 20,000 cases) in the spring of 1942.¹⁰⁶ Although disease onset was spread over time, when the common source was recognized and cases were plotted from the time of initial immunization with 17D vaccine, they formed a classical log-normal distribution (Fig. 12.10) that provided a definitive estimate of the distribution of incubation period for hepatitis B. Although this epidemic was originally considered to be one of hepatitis A, the great length of the incubation period (mean of 14 weeks) and the absence of secondary spread to contacts provided strong epidemiologic evidence that this disease was a distinct entity.

An outbreak of hepatitis A occurred in 1961 in Pascagoula, Mississippi.⁷³ In some cases, detailed food histories were taken that showed, by comparison with controls, that there was an association with raw oysters. Subsequent investigation disclosed that certain oyster beds in Pascagoula Bay were located near the discharge point for inadequately treated sewage from the city, and cases were associated with oysters supplied from these beds. This was one of the first instances of shellfish-associated hepatitis A, and it was later demonstrated that oysters, through their siphoning system, are capable of concentrating virus up to 1,000-fold. One of the largest outbreaks of hepatitis A virus infection associated with shellfish in the United States within the past two decades occurred in 2005 and involved 39 people.¹⁰ This was the first such outbreak in which identical viral genetic sequences were demonstrated in both cases and food products.

FIGURE 12.10. Distribution of incubation periods for a common source epidemic of vaccine-associated hepatitis B. The graph shows cases of jaundice tabulated by weeks from immunization with 17D yellow fever vaccine to onset for military units in California. (Data from Sawyer WA, Meyer KF, Eaton MD, et al. Jaundice in army personnel in the western region of the United States and its relation to vaccination against yellow fever. *Am J Hyg* 1944;39:337–387.)

Propagated Epidemics

Propagated epidemics, as the term implies, involve host-to-host spread of virus. The occurrence of an epidemic is therefore owing to the action of three parameters that determine clinical disease incidence—namely, the proportion of the population susceptible, the proportion of infected (and infectious) individuals, and the case infection ratio. To produce the unusually high incidence that defines an epidemic, at least one of these parameters must be operating above its usual level. In some but not all outbreaks, it is possible to implicate a specific parameter.

Measles incidence in Iceland over a 50-year period is shown in Figure 12.11, during which epidemics alternated with periods of complete absence of measles. In this extreme situation, the virus invades the population, spreads widely and quickly, and fades out when the concentration of susceptibles drops below the level needed to perpetuate the virus. The virus disappears entirely, allowing susceptibles to accumulate as new

FIGURE 12.11. Measles incidence in Iceland from 1900 to 1940. (Data from Tauxe R. Measles incidence in Iceland, 1900–1940. Unpublished report. 1979.)

cohorts of infants are born. Once enough susceptibles have accumulated, a single importation of measles can initiate a new epidemic. In this situation, the parameter critical for epidemic initiation is the proportion of susceptible individuals in the population.

By contrast, outbreaks of arbovirus disease are unrelated to the proportion of susceptibles, because infection is infrequent and a high proportion of the population is always susceptible (areas with hyperendemic yellow fever or dengue may represent exceptions). Epidemics are a reflection of the proportion of susceptibles who become infected. Because humans are terminal hosts who do not act as links in the infection chain, the key determinants are ecological factors that result in a high concentration of vectors and a high infection rate in the vector population. Epidemics are most commonly preceded by those climatic conditions (rainfall, temperature, and the like) that maximize the vector population.

In some instances, an outbreak is clearly associated with an increase in the ratio of cases to infections, often associated with a virus strain of high pathogenicity. Such occurrences are probably quite frequent but are rarely well documented. One well-studied example is the pandemic of avian influenza that overwhelmed the poultry industry of Pennsylvania in 1983. In this instance, there was a sudden increase in the virulence of an influenza virus, already enzootic in the poultry population, resulting in a pandemic that led to major commercial losses and was only controlled by a widespread slaughter program. Unusually, isolates of the virus from before and after the epidemic were available for analysis, and a classical series of studies showed that a point mutation in the viral hemagglutinin enhanced the replication ability and virulence of the virus.¹²⁶

Epidemics, Viral Pathogenesis, and Molecular Epidemiology

Expanding knowledge of basic virology provides molecular insights into the determinants of viral epidemics. In certain instances, it is possible to identify some of the molecular determinants of each of three parameters (proportion immune, proportion infected, and case infection ratio) that are responsible for propagated epidemics.

The proportion of the population immune is a relatively inflexible parameter for most viruses, with the exception of those against which vaccine exist. Influenza virus is a special instance. This virus is transmitted so effectively that it nearly exhausts the supply of susceptible hosts. The major antigenic protein of influenza virus is the viral hemagglutinin, which serves as the viral attachment protein and the target for neutralizing antibodies. Influenza virus has a genome composed of eight segments, and these segments may reassort when two type A influenza viruses co-infect the same cells, with the creation of viruses containing a mixture of segments from the two parents. On rare occasions, a human strain of virus reassorts with an animal strain and acquires the hemagglutinin of the animal virus. This leads to major shifts in the antigenicity of the virus, such as occurred in 1957, with the appearance of the Asian strain, which had an H2 hemagglutinin whereas previous influenza viruses had an H1 hemagglutinin, and in 2009, resulting in a complex, triple-reassortment H1N1 influenza virus.²⁰ Such a radical shift in antigenicity provides the newly created virus with a global population that is relatively susceptible; as a result, a worldwide influenza pandemic may occur.

TABLE 12.13 Comparison of Case Fatality Rates for Severe (Variola Major) and Mild (Variola Minor) Forms of Smallpox

Disease	Place and years	Cases	Deaths	Case fatality ratio per 100 (%)
Variola major	Minneapolis, 1924–1925	1,430	365	25.5
Variola minor	London, 1928–1934	13,686	34	0.2

From Marsden JP. A critical review of the clinical features of 13,686 cases of smallpox (variola minor). *Bull Hyg* 1948;23:735–746; and Sweitzer SE, Ikeda K. Variola, a clinical study of the Minneapolis epidemic of 1924–1925. *Arch Derm Syph* 1927;15:19–29.

The proportion of susceptibles infected will be determined by two characteristics of a given virus—namely, the generation time and the transmissibility. A virus with a relatively short generation time, such as influenza virus, can spread more rapidly than a virus such as poliovirus despite its lower transmissibility (R_0 for influenza virus is approximately 2 compared to 5–7 for polioviruses). Generation time and transmissibility determine the kinetics of the infection and are related to the titers of virus excreted; these parameters may be influenced by specific viral genes. Analysis of the genetic determinants of reovirus transmission demonstrated that the $\lambda 2$ spike protein encoded by the L2 gene segment is a major determinant of transmissibility.⁵³ Likewise, the transmission of California serogroup bunyaviruses, by their mosquito vector, *Aedes triseriatus*, is determined by the middle RNA segment, which encodes the viral glycoproteins.⁴²

A major determinant of the case infection ratio is viral pathogenicity. Most viruses exhibit great natural variation in pathogenicity. One classical example is variola virus, which caused virulent forms of smallpox (variola major) in India and Africa and much milder disease (alastrim or variola minor) in South America (Table 12.13). It was known for many years that natural isolates of poliovirus varied greatly in their neurovirulence, and attenuated isolates were the starting point for the development of avirulent vaccine strains. Molecular analysis identified the genomic determinants of virulence, which are located both in the structural genes and in the noncoding 5' region of the genome.⁸³ This natural variation might have been a factor in the severity of poliomyelitis epidemics of the past. Another example is the 1983 pandemic of avian influenza cited previously, which was traced to a point mutation that increased the cleavability of the hemagglutinin molecule, thereby enhancing viral maturation and infectiousness with dramatic epidemiologic consequences.¹²⁶

Molecular epidemiology has permitted the unraveling of otherwise enigmatic epidemiologic events. Poliomyelitis was eradicated from many countries, and outbreaks were relatively unusual. However, numerous outbreaks have been traced to revertant strains of oral poliovirus vaccine (OPV), resulting in vaccine-associated poliomyelitis. The genealogy of these revertant viruses was determined by their genomic sequences to be closely aligned with OPV strains but were distinctly different from circulating strains of wild-type poliovirus.⁷⁶

Phylogenetics

Infectious disease epidemiologists are increasingly interested in linking evolutionary and epidemiologic processes, a field

referred to as phylodynamics.⁴⁰ Because of the high mutation rates of viral pathogens, evolutionary and epidemiologic processes take place on a similar time scale.⁹⁷ According to this framework, phylodynamic processes that determine the degree of viral diversity are a function of host immune selective pressures and epidemiologic patterns of transmission.

PERPETUATION AND ERADICATION OF VIRUSES

All viruses, whether they cause acute or chronic infections, are capable of persisting in populations because perpetuation is a requirement for survival. Eradication is the converse of perpetuation and represents the ultimate method for control of an infectious disease. To determine the potential for eradication, it is necessary first to understand the requirements for perpetuation.

The principal ecological patterns of viruses in host populations have been discussed previously, with emphasis on human viruses. In most instances, a virus is perpetuated in a single species, and discussion will be limited to this dominant ecological pattern. Parameters that determine perpetuation include population variables and viral variables.⁴ Population determinants include (a) the size of the population, (b) the turnover rate (rate at which susceptibles are introduced), (c) the density of the population, and (d) the proportion of the population susceptible. Viral determinants include (a) transmissibility, (b) generation time, and (c) duration of infectiousness (acute or persistent). These three viral variables determine the rate of spread of a virus through a population (for a given set of population parameters). Paradoxically, an agent that spreads rapidly may exhaust susceptibles and disappear more quickly from a small population than a virus that moves indolently through the same population. Perpetuation will be discussed separately for large and small populations, because population size is such an important determinant.

Small Populations

For small populations, a crude prediction of perpetuation may be made by determining the number of susceptibles entering the population per generation period. If this number is less than one, persistence will almost certainly not occur.¹³²

Isolated Human Populations

Small primitive human populations that have minimal contact with the outside world are occasionally available for serological

FIGURE 12.12. Age-specific prevalence of antibodies to poliovirus types 1, 2, and 3 in an isolated Eskimo village in Greenland. (Data from Paffenbarger RS, Jr., Bodian D. Poliomyelitis immune status in ecologically diverse populations, in relation to virus spread, clinical incidence, and virus disappearance. *Am J Hyg* 1961;74:311–325.)

study. These populations provide a unique opportunity to determine the ability of viruses to perpetuate in their natural hosts. There are two principal patterns.¹¹ Viruses that cause acute short-term infections produce abrupt outbreaks after introduction into human populations and then die out until reintroduced. Viruses that are capable of persisting in individual hosts are able to perpetuate in small isolated groups.

Figure 12.12 presents the age distribution of antibodies to poliovirus types 1, 2, and 3 in an isolated Eskimo village. The profiles show that type 1 virus had infected essentially the entire population 25 years before the study, type 2 virus had caused a similar wave of infections 15 years before the study, and type 3 virus had been present shortly before the collection of sera. In addition, it is clear that following its intrusion, each virus disappeared from the population, because there were few people younger than 25 years of age with type 1 antibody (the few seropositive individuals probably represent cross-reacting antibody following type 2 infection) and few younger than 15 years of age with type 2 antibody.

In contrast, hepatitis B virus produces a considerable proportion of persistent infections, particularly in primitive populations, where infection occurs early in life. Figure 12.13, from another study of Eskimos, shows that infections occurred at all ages, with a gradual rise in cumulative incidence to 60% by 60 years of age, with no evidence of disappearance of virus from the population or of exhaustion of susceptibles. The curve for hepatitis B surface antigen indicates that there were many persistently infected carriers in the population accounting for perpetuation in this small community.

Small Animal Populations

Animal populations differ radically from human populations in their relatively rapid rate of turnover—a critical variable in virus perpetuation. Mean life expectancy in many animal populations ranges from 6 to 12 months, in contrast to a range of 30 to 70 years for humans. However, the kinetics of infection are similar in an individual human or animal host.

FIGURE 12.13. Age-specific prevalence of hepatitis B antibodies (anti-HBs) and hepatitis B surface antigen (HBsAg) in Eskimos in southwest Greenland. (Data from Skinhoj P. Hepatitis and hepatitis B-antigen in Greenland. II: Occurrence and interrelation of hepatitis B associated surface, core, and “e” antigen-antibody systems in a highly endemic area. *Am J Epidemiol* 1977;105:99–106.)

For instance, the median incubation period (to rash) is about 14 days in smallpox and 10 days in mousepox. The consequence is that perpetuation may occur in animal populations (with rapid turnover) that are much smaller than the minimum human population required to sustain a similar virus.

Laboratory animal colonies have provided an opportunity to document the quantitative impact of population turnover. Perpetuation in such colonies is of more than academic interest, because enzootic infections present an important practical problem that frequently confounds biomedical research. One documented example is ectromelia (mousepox) that closely resembles variola in humans.²⁴ Infection is initiated either by entry through the skin or by inhalation and results in a generalized pox-like rash of the skin from which aerosolized virus is transmitted. As in smallpox, infections can be fatal, although recovered mice are solidly immune. Ectromelia is a relatively infectious agent and a notorious cause of acute and devastating epizootics. When a few infected mice are placed in a larger group of susceptible animals, the virus spreads rapidly, all mice are infected within two incubation periods, and many mice die.

In these circumstances, ectromelia would not be expected to perpetuate in a small mouse population. However, a series of classical studies demonstrated that this virus was readily perpetuated in a population of 100 to 200 animals.³⁷ In one representative experiment, a mouse colony was established with 25 normal and 20 infected mice, and 3 uninfected mice were added daily; animals were removed only if dead. During a 30-month observation period, the total colony size gradually rose to a constant level of about 230 animals. The infection was maintained throughout the observation period; at equilibrium, about one-fifth of the mice were uninfected, one-fifth were actively infected (mortality rate, 50% to 60%), and three-fifths were recovered immune animals. It was possible to maintain this acute highly lethal virus over long periods of time in mouse populations with as few as 70 animals, demonstrating that high turnover markedly reduces the population size required for perpetuation.

TABLE 12.14 Fadeouts of Measles in North American Cities, 1921–1940^a

Size of city (millions)	Number of cities	Average annual measles reports (thousands)	Years of study	Years with fadeout
1.0–7.5	6	3.5–21	120	0
0.5–0.9	9	2.8–4.0	180	1
0.2–0.3	5	0.9–2.1	100	56

^aEstimate of reporting ranged from 14% to 55% of measles incidence. *Large cities*: New York, Chicago, Philadelphia, Detroit, Los Angeles, Montreal; *medium cities*: Cleveland, Baltimore, Boston, Toronto, Washington, Pittsburgh, Milwaukee, Buffalo, Minneapolis; *small cities*: Vancouver, Rochester, Dallas, Akron, Winnipeg.

From Bartlett MS. The critical community size for measles in the United States. *J R Stat Soc A* 1960;123:37–44; and Yorke JA, London WP. Recurrent outbreaks of measles, chickenpox and mumps. II. Systematic differences in contact rates and stochastic effects. *Am J Epidemiol* 1973;98:469–482.

Large Populations

To follow the pattern of viral infection in large populations, it is generally necessary to rely on reportable diseases that can be identified from clinical observations and that exhibit relatively high case infection ratios. Measles is one of the few viral diseases that meets these criteria; however, even measles surveillance has its limitations, considering only a fraction (usually 10%–50%) of cases are reported. Table 12.14 shows that in cities of 200,000 to 300,000, measles faded out for at least 1 month in 56 of the 100 years recorded. Because a population of 300,000 might be expected to experience about 5,000 cases of measles in an average year, it is initially surprising that this would be insufficient to maintain measles virus transmission. The explanation becomes more apparent when the seasonal cycle of measles is examined.^{66,131,132} Data for the city of Baltimore (population 900,000) for 32 years of observation showed that annual reports averaged about 5,000 cases, representing about 35% of cases; incidence rates ranged more than 100-fold from the peak in March to the seasonal low in August, when about 10 cases were reported. Because there were about three generation periods per month, this represents no more than 3 cases per generation period, which is barely sufficient to perpetuate the virus. A similar city of 300,000 would experience only 1 case per generation period at the seasonal trough; in such an instance, it is quite plausible that periodic fadeouts would occur.

This analysis suggests that persistence of a short-cycle infection in a large population depends on the relationship between incidence during the seasonal trough and the generation time. Influenza virus, with a generation time of 1 to 3 days, has difficulty persisting in human populations through the seasonal trough but circumvents the problem by shuttling between Northern and Southern hemispheres each year.

Requirements for Eradication

The history of smallpox, and more recently rinderpest virus, demonstrates that eradication is an attainable objective for selected human and animal viral infections. The salient epidemiologic features that made smallpox eradication possible were its relatively long incubation period (about 14 days) and low infectiousness, the near equivalent durations of the latent and incubation periods, its marked seasonality, a case to infection ratio approaching 1, and the lack of an extrahuman reservoir.⁴⁹ These features made it possible to abandon mass

vaccination in favor of a search-and-containment strategy in which local outbreaks were identified and aborted by intensive immunization around each focus.³¹ The few local outbreaks during the seasonal trough were essential to the success of this strategy.

Eradication of Polioviruses

Two poliovirus vaccines (inactivated poliovirus vaccine [IPV] and OPV) were introduced in the period from 1955 to 1963 in the United States, and their application led to the elimination of circulating wild polioviruses around 1970.^{84,85} Wild polioviruses were eliminated from the Western Hemisphere by 1990 as a result of immunization programs in Latin America, and the World Health Organization set a goal of global eradication in 1988. Worldwide efforts reduced polio cases from an estimated 350,000 in 1988 to fewer than 1,000 in 2000. However, since then, elimination efforts have stalled at a level of 1,000 to 2,000 cases annually, owing to the persistence of wild polioviruses in a few countries: Nigeria and a belt extending from Afghanistan east across Pakistan to northern India. There have been two major impediments in these countries, first the failure to immunize a sufficiently high proportion of infants and young children in settings where transmission of enteric infections is very intense and, second, a low “take” rate of OPV, owing in part to competition between the three serotypes in the vaccine. The latter problem was solved in part by the introduction of monovalent (type 1) and bivalent (types 1 and 3) OPV, whereas concentrated efforts to increase immunization rates have reduced circulating polioviruses in Nigeria and India.¹⁶ At this writing (2011), it is unclear whether these efforts will eliminate residual circulation wild polioviruses, particularly in areas of Pakistan and Afghanistan where there is a breakdown of civil society.

OPV presents another complicating issue, namely the tendency to revert to a more virulent phenotype on human enteric passage. Vaccine-derived polioviruses have caused about 15 documented outbreaks of poliomyelitis in settings where weak immunization programs have left many children susceptible and capable of spreading OPV shed by those who were immunized. Most of these outbreaks have been quite small; however, an outbreak in Nigeria attributable to revertant type 2 vaccine-derived poliovirus has caused nearly 300 paralytic cases over a period of 5 years.¹²⁴ The potential dangers of OPV have led many industrialized countries to shift from OPV to IPV, and

some experts believe that the world will not be freed from paralytic poliomyelitis until immunization with OPV is ended.⁸⁵

Eradication of Measles Virus

Remarkable progress has been made in reducing global measles incidence and mortality as a consequence of measles vaccination. In the Americas, intensive vaccination and surveillance efforts interrupted endemic transmission of measles virus, in part based on the successful Pan American Health Organization strategy of periodic nationwide measles vaccination campaigns and high routine measles vaccine coverage. In the United States, high coverage with two doses of measles vaccine eliminated endemic measles virus transmission in 2000. More recently, progress in reducing measles incidence and mortality has been made in sub-Saharan Africa and Asia as a consequence of increasing routine measles vaccine coverage and provision of a second opportunity for measles vaccination through mass measles vaccination campaigns. The feasibility of measles eradication has been discussed for more than 30 years, beginning in the late 1960s when the long-term protective immunity induced by measles vaccines was becoming evident.¹⁰⁸ Three biological criteria are deemed important for disease eradication, including measles virus: (a) humans are the sole pathogen reservoir; (b) accurate diagnostic tests exist; and (c) an effective, practical intervention is available at reasonable cost.¹ Interruption of transmission in large geographical areas for prolonged periods further supports the feasibility of eradication. Measles is thought by many experts to meet these criteria.⁸⁹

Several potential biological obstacles to measles eradication should be considered.⁷⁹ Persistent infection with transmissible measles virus would pose a biological barrier to eradication. Measles virus is known to establish persistent infection in persons with subacute sclerosing panencephalitis (SSPE); however, virion assembly and budding is defective and multiple mutations occur throughout the measles virus genome.³³ As a consequence, infectious measles virus is not present. Theoretically, selective pressure on measles viruses to mutate neutralizing epitopes and escape protective immune responses induced by vaccines could be a biological obstacle to measles eradication. However, despite the high degree of genetic variation expected of an RNA virus, mutations in the measles virus genome have not reduced the protective immunity induced by measles vaccines.¹¹⁹ Subclinical infection resulting in sustained measles virus transmission also could pose a barrier to eradication,⁸⁰ as it has for polioviruses. However, sustained measles virus transmission among partially immune individuals without clinical disease would be highly unlikely.⁶¹

Eradication of Rinderpest Virus

Rinderpest virus, a pathogen of cattle and many other domestic and wild artiodactyl species, was declared eradicated on May 25, 2011, following widespread vaccination and control efforts coordinated by the Global Rinderpest Eradication Programme.⁷⁷ Rinderpest virus is a *Morbillivirus* closely related to measles virus, transmitted by close contact with an infected animal via inhalation of virus-containing nasal, oral, or fecal secretions. Infection resulted in severe diarrhea leading to dehydration and death. Rinderpest impacted on human health in Europe and Africa by decimating cattle populations, leading to famine, disease, and death.

What is remarkable about rinderpest eradication is that the virus has many potential reservoirs, both domestic and wild, and yet the goal of eradication was achieved through widespread vaccination of cattle and buffalo, establishment of effective surveillance programs, and regional coordination of control efforts.

APPLICATIONS OF EPIDEMIOLOGY

Identification of Etiological Agents

Viruses that cause acute infections, are readily transmitted, and cause intense outbreaks, are often first identified as distinct clinical entities during epidemiologic studies. Examples include HIV (AIDS), hantavirus (pulmonary syndrome), WNV (encephalitis), SARS-coronavirus, and the 2009 H1N1 influenza virus. Epidemiologically, it may be difficult to infer whether the cause is a virus or other infectious agent. Epidemiologic observations, however, may suggest the portal of virus shedding and the period of infectiousness, which is important for the collection of specimens for isolation.

Epidemiologic observations may also contribute insights into more obscure persistent infections associated with atypical chronic diseases. The spongiform encephalopathies or prion diseases are an example. This group of agents includes scrapie of sheep, kuru and Creutzfeldt-Jakob disease of humans, and BSE.¹⁷ The initial definitive evidence that scrapie, a chronic degenerative neurological disease, could be transmitted by an infectious agent and occurred as an unwanted complication of the use of louping ill vaccine in Scotland in 1935.³⁸ Table 12.15 shows that three lots of vaccine against louping ill, a flavivirus, were injected into sheep in Scotland. Unexpectedly, there was a very high incidence of scrapie in recipients of one of the three lots. Subsequent epidemiologic investigation showed that louping ill vaccine was prepared by formalin treatment of virus grown in sheep brain and that several of the sheep used were probably incubating scrapie because their parents subsequently came down with the disease. Prions are extremely resistant to inactivation by formalin; thus, contamination of the vaccine was readily explained. Prior to this episode, it was not generally accepted that scrapie was attributable to a transmissible agent with an incubation period of several years.

TABLE 12.15 Occurrence of Scrapie in Sheep Immunized with Louping Ill Vaccine, Scotland, 1935^a

Vaccine batch	Number of sheep vaccinated	Percentage with scrapie
1	>22,000	<0.1%
2	18,000	5%
3	>4,000	<0.1%

^aBatch 2 was prepared from 122 sheep infected with louping ill; of these, 8 were offspring of scrapie-affected ewes. Interval between subcutaneous injection of vaccine and onset was 20 months or longer.

From Greig JR. Scrapie in sheep. *J Comp Pathol* 1950;60:263–266.

Evaluation of Vaccine Efficacy and Safety

The ultimate test of viral vaccines is their efficacy and safety in humans. Epidemiology provides well-established methods for the design and analysis of prospective studies of vaccine efficacy.⁴⁴ These are illustrated by the 1954 field trial of poliomyelitis vaccine.⁷¹ In this trial, a large number of children in the first three grades of elementary school were enrolled. As shown in Table 12.2, the trial comprised two different study designs—namely, placebo and observed. In the placebo design, children fell into three categories: vaccinated, placebo inoculated, and nonvolunteers (uninoculated). In the observational study, the three groups were vaccinated second graders, nonvolunteer second graders (unvaccinated), and controls (all children in the first and third grades). The most valid comparison was between vaccinated and placebo-inoculated children in the placebo areas: This group yielded an estimated efficacy of 72% for paralytic poliomyelitis, whereas the observed control area yielded an efficacy of 63%. The discrepancy was explained by the fact that the nonvolunteer children in both areas experienced an attack rate that was considerably lower than that of the placebo controls or the observed controls. Apparently, volunteer children were at higher risk (presumably because they included a higher percentage of susceptibles) than were nonvolunteer children. Thus, the strict placebo control was the best comparison group. When the placebo study was further refined by limiting the analysis to laboratory-confirmed cases, the estimated efficacy was even higher (85%), underlining the importance of etiology-proven cases in vaccine evaluation.

Epidemiologic studies can also play a vital role in documenting vaccine complications. The occurrence of Guillain-Barré syndrome associated with the use of swine influenza virus vaccine in the fall of 1976 provides a good illustration.¹⁰⁷ About 40 million people received influenza vaccine in a mass campaign. Cases of a relatively rare neurological disease, Guillain-Barré syndrome, were reported in vaccinees at a frequency considered excessive, and the vaccine was withdrawn. When vaccine-associated cases were compiled by interval after immunization (Fig. 12.14), they exhibited a log-normal distribution typical of many incubation periods. This pathognomonic epidemiologic feature, along with the excessive rates seen during the early weeks after immunization, provided strong evidence of an association and justified termination of the vaccine program. Epidemiologic evidence was the key in this episode because the association (<1 case per 100,000 vaccinees) was only detectable in a massive field study. Because Guillain-Barré syndrome occurs at a baseline rate in the population and those cases associated with the vaccine were not clinically distinguishable from the baseline cases, this episode presented a special epidemiologic challenge. The occurrence of Guillain-Barré syndrome was not predictable by any small-scale human trial or laboratory test, and the biological explanation is still unclear. In fact, epidemiologic studies conducted with influenza vaccines used after 1976 have demonstrated that these vaccines (produced from nonswine strains of virus) apparently carry no risk of Guillain-Barré syndrome.⁵⁸ Nevertheless, the importance of epidemiologic studies to determine background rates of disease remains critical to assessing the risk of adverse events associated with vaccines. In considering mass vaccination against the 2009 H1N1 influenza virus, it was estimated that if a cohort of 10 million individuals were

FIGURE 12.14. Guillain-Barré syndrome (limited to cases with extensive involvement) associated with swine influenza vaccine, according to the interval between immunization and onset in the United States in 1976. Two baseline rates are shown to define the expected rate of spontaneous Guillain-Barré syndrome. The period of the epidemic is readily defined (1–6 weeks after immunization) and the intervals during this period of excess incidence form a classical log-normal curve. (Data from Langmuir AD, Bregman DJ, Kurland LT, et al. An epidemiologic and clinical evaluation of Guillain-Barre syndrome reported in association with the administration of swine influenza vaccines. *Am J Epidemiol* 1984;119:841–879.)

vaccinated in the United Kingdom, 21.5 cases of Guillain-Barré syndrome and 5.75 cases of sudden death would be expected to occur within 6 weeks of vaccination as coincident background cases.¹²

Development and Assessment of Control Measures

In addition to vaccines, other control measures are sometimes useful against viral infections. Such approaches seek to reduce the risk of exposure and are usually suggested by epidemiologic studies of transmission mechanisms. Examples include reduction of risk associated with blood or blood products for viruses such as hepatitis B and hepatitis C, HIV, and human T-cell leukemia viruses I and II. Another classical example is the reduction of urban yellow fever and dengue through control of *Aedes aegypti* mosquito populations. The use of epidemiologic management of viral infection is illustrated by a study of Bolivian hemorrhagic fever—an arenavirus that was endemic in certain rural villages.⁵¹ Ecological studies suggested that this virus was enzootic in one species of peridomestic house-dwelling mouse—*Calomys callosus*—and was transmitted by aerosolized fomites. Table 12.16 shows a study in which rodent control was initiated in one-half of a village and then extended to the other half. The dramatic effect of rodenticides confirmed the hypothesis of the virus reservoir and its transmission mechanism and provided a practical approach to control of a serious viral infection. More recently, sophisticated mathematical models have been used to evaluate control measures that cannot be tested in epidemiologic studies, including containment of a potential bioterrorist use of smallpox virus⁴³ and containment of pandemic influenza virus through vaccination¹³⁰ and the use of prophylactic antivirals.²⁵

OVERVIEW

Medical Importance of Antiviral Drugs and Barriers to Their Development

Viruses are a leading cause of disease and death worldwide. Although public health measures and vaccines are the most effective ways to control many viral infections, preventive measures have not succeeded for numerous viral diseases. For some of these diseases, antiviral drugs have been developed. A number of these drugs have been highly successful, saving lives and relieving suffering. This has been most dramatic with

drugs that are active against human immunodeficiency virus (HIV). In the developed world, these drugs have transformed a progressive fatal disease into a manageable condition, in which virus replication can be suppressed presumably for a lifetime as long as antiretroviral therapy is maintained. These dramatic benefits had been extended to more than 7 million people globally by 2011.¹⁸²

Despite these successes, there are still relatively few diseases for which highly effective antiviral drugs have been developed. There are several factors that contribute to this. With very few exceptions, such as the polymerases of related viruses, drug targets are virus specific, and therefore only a few antiviral drugs developed against one virus have been active against other viruses. Some viruses (e.g., herpesviruses, HIV) establish latent infections, so treating active infections does not cure the patient. Different viruses, especially respiratory viruses, can cause similar symptoms, making diagnosis difficult. Often, treatment must begin early to be beneficial, sometimes because the viral diseases are quickly controlled by immune responses.

On top of these factors are economic issues that have often discouraged pharmaceutical companies from developing antiviral drugs. For example, any individual virus disease may represent a relatively small potential market. It is not surprising then that companies have focused mainly on easily diagnosed and chronic viral diseases that require prolonged drug administration and that are relatively widespread in developed countries, because these are diseases for which treatment would earn substantial profits. Perhaps ironically, these diseases are often caused by viruses that establish latent infections and are not curable.

The first highly successful antiviral drug was acyclovir (ACV), initially developed in the late 1970s against herpes simplex virus (HSV) 1 and 2 and varicella zoster virus (VZV).⁹¹ Antiviral drug discovery expanded markedly with the acquired immunodeficiency syndrome (AIDS) epidemic, which led to a variety of drugs against HIV and opportunistic pathogens such as human cytomegalovirus (HCMV). This coincided with expanding knowledge about virus genetics, molecular biology, enzymology, and protein structure, which permitted modern, more rational approaches, to drug discovery. Indeed, antiviral drugs have been a proving ground for these approaches.

The Process of Antiviral Drug Development

Older antiviral drugs such as amantadine and ACV were discovered by the testing of chemicals for their ability to inhibit virus replication in labor- and time-intensive assays of viral replication, such as assays of cytopathic effect or plaque assays.^{75,327} These chemicals had typically been synthesized for some other

purpose, and discovery of their antiviral activities was often serendipitous. When particular chemicals were known to have antiviral activity, a variety of other chemicals with similar structures were tested for activity. Several examples of this somewhat more rational procedure can be found in the sections on specific drugs.

The more modern and rational approach of high-throughput screening of large libraries of chemicals has been used to discover some newer drugs. High throughput screens can be “target-based” or “cell-based.” Target-based screens start with the identification of a viral gene product that would make a good drug target (see below for discussion). It is important that the target protein can be expressed at high levels and purified, and that it can be assayed rapidly with high-throughput robotic technology. Such target-based screens can examine more than one million chemical compounds in no more than a few weeks. Most nonnucleoside reverse transcriptase inhibitors (NNRTIs), which are active against HIV-1, were discovered using this approach (e.g., nevirapine²⁴⁶). Cell-based high-throughput screens are slower, more cumbersome, and more expensive. However, such assays permit interrogation of multiple and unappreciated mechanisms of action, and can be performed relatively rapidly using robots (i.e., within one to a few days per assay). In addition, they automatically identify compounds that can enter cells and block a step of virus replication. Highly potent compounds that target a poorly understood function of hepatitis C virus (HCV) and block HCV replication *in vivo* have been discovered using a cell-based screen.¹¹⁰

A still more rational approach is to exploit detailed knowledge about a viral protein to design drugs that will inhibit its activity. In particular, knowledge of the three-dimensional structure of the protein can enable visualization of its active site and understanding of its mechanism of action, and can also be used to design or refine small molecules that can block the active site and the protein's action. An example of a drug discovered using this approach is the neuraminidase inhibitor, zanamivir, which is active against influenza A and B viruses.³⁷⁰

The approaches outlined in the preceding text result in what is called a “hit”; however, a hit is only an inhibitor of the function of a viral protein or of viral replication in cell culture. The next steps involve using medicinal chemistry to convert the hit into a compound with high potency and desirable pharmacological properties (e.g., bioavailability, long elimination half-life, low toxicity), not to mention patentability. If the structure of the hit compound bound to its target is available, this information can be used to help generate additional compounds to be tested. This process will be illustrated below with the example of the anti-HIV protease inhibitor, ritonavir. Simultaneously, studies to demonstrate the mechanism(s) of action of the compounds are undertaken (see section on antiviral drug mechanisms and drug resistance below). A key, but often overlooked aspect of drug development is developing optimal methods for synthesis of pure compound on a large scale and formulation of the compound for administration to humans.

When a candidate compound with desirable properties has been developed, clinical trials begin. There is no rigid formula by which an antiviral candidate is assessed after it enters the clinic. Typically, the process of clinical development starts with the administration of drug in escalating doses to small

cohorts of volunteers to assess pharmacokinetics and tolerability (phase I trials). With some virus infections, these studies may be performed in patients in whom drug activity can also be assessed, for example by quantifying reductions of chronic HCMV shedding in the genitourinary tract or of HCV in the plasma (proof-of-concept studies). Substantial reductions in viral load encourage progression to more advanced clinical trials. However, with an infection such as HIV, the risk of selecting for drug resistance that might compromise future treatment options often restricts phase I trials to studies of HIV-seronegative subjects. This issue may become important for other viruses (e.g., HCV).

A major advantage of antiviral drug development, compared to drug development for many other diseases, is that quantitative reductions in virus shedding are a precise measure of activity and in general correlate with clinical end points. These quantitative reductions can be measured quickly (days) and permit determination of whether drugs work and of appropriate doses and dosing intervals. Phase II clinical trials assess this antiviral activity along with additional pharmacological and safety information in dozens to several hundred subjects. The data from phase II trials permit the design of larger phase III registrational studies, which provide statistically robust results that fulfill regulatory requirements for drug approval. Trials for drugs for influenza and herpesviruses infections require clinical end points (i.e., amelioration of disease), with virological data supporting those. For HIV, and increasingly for hepatitis B virus (HBV) and HCV, the correlations between levels of viremia and disease, and the correlations between drug-induced reductions in viremia and improvement of disease have resulted in virological end points (quantitative reduction and proportion of patients below the limit of detection) as criteria for drug approval.

Phase III studies of a new antiretroviral drug can pursue two general indications. For patients who failed prior regimens because of drug-resistant virus and who have limited treatment options, an accelerated approval process is available with shorter trials to document efficacy. Historically, patients were randomized to an optimized regimen based on the results of a drug resistance test with or without the addition of the test drug that presumably has activity against drug-resistant virus. Demonstration of superior virological end points after 24 weeks with continued follow-up for at least a year was considered supportive of an unmet medical need to fulfill criteria for registrational approval. Repeated demonstrations that this approach worked have led to the sense that placebo arms were no longer ethically defensible. The proper design of future trials for these patients remains unclear.²⁰⁶

Development of a drug for first-line (initial) therapy faces higher hurdles. Patients starting antiretroviral therapy are now usually asymptomatic and must plan for decades of successful suppression of virus replication. Therefore, a new drug must offer superiority to the current standard of care, and a combination including a new drug “X” (for example, tenofovir and emtricitabine [FTC] plus drug X) might be compared to tenofovir and FTC plus efavirenz. Hundreds of subjects in each arm must be followed for at least 2 years for efficacy and safety to fulfill regulatory criteria for approval of a drug for use in initial treatment. A predefined statistical definition of “non-inferiority” is the criterion for approval of candidate drugs for which there is an approved drug in the same class,

Should the clinical trials yield the desired results, the “hit” will have turned into an approved drug. Even then, its efficacy and safety will be put to the test in much larger populations, and new indications for its use may emerge.

Importance of Antiviral Drugs for Basic Science

Aside from their importance in treating viral diseases, antiviral drugs make excellent laboratory tools. As is illustrated in detail later in this chapter, drugs can block the functions of specific viral proteins and thus specific stages in viral replication. This is crucial for understanding the timing of particular events in the virus replication cycle and which proteins are needed for each step. Studies using selective antiviral drugs, coupled with viral mutations that confer drug resistance, can help to identify the roles of viral proteins and dissect the details of how these proteins function. Drug-resistance mutations can provide selectable markers for engineering interesting mutant viruses and performing viral genetics.

Examples of how studies of antiviral drugs and drug resistance can illuminate virus biology and biochemistry include the role of amantadine in the discovery of an influenza A ion channel and its function in virus uncoating,^{142,289} and the role of ganciclovir in the discovery of an unusual HCMV protein kinase that can phosphorylate nucleoside analogs.³⁵⁰ Crystal structures of drug targets with bound inhibitors have yielded important insights into structure and function of these targets. For example, the first structure of a retroviral (HIV) reverse transcriptase was obtained in complex with nevirapine.¹⁹³ Similarly, clinical investigation has been greatly abetted by antiviral drugs. Intensive monitoring of the dynamics of HIV replication following the administration of drug has permitted important insights about rates of virus production, virus clearance, and cellular sources of virus replication.^{129,282} Studies of patients receiving HIV therapy have elucidated much of our understanding of HIV latency, evolution, and fitness.^{50,98,390} Finally, the remarkable restoration of CD4 cell numbers and function with HIV therapy provides insights regarding both lymphocyte dynamics and immune function.^{7,129}

General Aspects of Antiviral Drug Mechanisms and Drug Resistance

Drug Selectivity, Resistance, and Drug Targets

The value of antiviral drugs to basic science depends on how selective they are and on how well their mechanisms are understood. Selectivity and mechanism are also crucial for the clinical use of antiviral drugs. Biologically, selectivity is the difference between the dose of the drug that exerts its antiviral effect (usually quantified as the dose that reduces viral activity by 50%) and the dose that exerts its cytotoxic effect (or more subtle impairments of the host). Examples of how selectivity is achieved biochemically can be found among the descriptions of the mechanisms of specific antiviral drugs.

It is generally agreed that the best way to understand antiviral selectivity and mechanism is through the study of drug resistance. Because viruses are obligate intracellular parasites, the detection of resistance to an antiviral drug implies that the drug is selective. That is, the drug acts at least in part by interfering directly with a virus-specific process, rather than by incapacitating the host cell.¹⁵⁷ In much the same way, a mutation in a viral gene that confers resistance to an antiviral drug

implies that the gene or its product is necessary for at least part of the selective action of the drug. It is not enough to identify a mutation in a drug-resistant mutant to show that the mutation confers resistance. It is crucial to perform a genetic experiment (e.g., reconstruct a virus with the mutation [and no other] and show that the reconstructed virus is drug-resistant).

In most cases, drug-resistant mutations identify targets of antiviral drugs. However, not all drug-resistant mutations identify drug targets. For example, inhibitors of influenza virus neuraminidase (e.g., zanamivir) can select for mutations in the gene encoding hemagglutinin.^{125,241,341} These mutations would be expected to result in a hemagglutinin that binds less avidly to cell surface glycoproteins. This in turn could result in a reduced requirement for neuraminidase to release the virion from the cell, and thus resistance to the neuraminidase inhibitor. Accordingly, genetics alone is not sufficient to identify a drug target. Ideally, one should also show that the drug interacts with the target, and that the resistance mutation results in a target with an altered interaction with the drug that explains the resistance phenotype. This usually requires biochemical studies, and the analyses are not always straightforward.

Genetics alone is also not sufficient to reveal the detailed mechanism of action of an inhibitor. Mapping a resistance mutation that results in a single amino acid change in the target protein identifies that residue as being necessary for sensitivity to the drug. Other genetic approaches, such as the generation of chimeric genes from closely related viruses that are susceptible or resistant to a drug (e.g., HIV-1 and HIV-2, and NNRTIs⁶⁷), can identify residues that are sufficient to confer susceptibility to the drug to an otherwise resistant protein. However, these results do not identify residues that interact with the drug. Identification of a drug-binding site requires methods such as photoaffinity cross-linking and x-ray crystallography. These two methods have identified the binding site for the NNRTI, nevirapine, on HIV-1 reverse transcriptase (RT).^{62,193,392} Mapping a drug binding site is valuable, but does not tell us how drug binding exerts its physiologic action. In the case of NNRTIs, pre-steady-state kinetic analyses of HIV-1 RT were used to show that the drug slows the enzyme's incorporation of deoxynucleoside triphosphates (dNTPs) into DNA,^{313,338} presumably by altering the orientation of catalytic residues, as suggested by the location of the drug binding site.¹⁹³ Therefore, solving the mechanism of action of an antiviral drug requires multidisciplinary approaches.

For a number of antiviral drugs, we still lack a complete understanding of their mechanisms of action and resistance, and, in some cases, there is considerable controversy regarding these mechanisms. This can even be true for drugs that are designed against a specific target. For example, fomivirsen is an oligonucleotide drug that is designed to inhibit HCMV replication by its complementarity to messenger RNA (mRNA) for an important regulatory protein.^{3,8} However, studies of a drug-resistant mutant did not confirm this mechanism of action.²⁶² Therefore, the mechanism of fomivirsen remains unknown. We will not discuss this and certain other drugs such as the anti-HSV topical treatment, docosanol, whose mechanisms are unknown.

General Aspects of Antiviral Drug Targets

There are two major kinds of virus proteins that serve as antiviral drug targets. In general, it is easier to inhibit a protein's

function (with an antagonist) than to promote its function (with an agonist). Therefore, the most common antiviral drug target is a virus-encoded protein that can be inhibited by a drug. Ideally, this kind of target should be essential for viral replication. Less ideally, it should at least be very important for replication and pathogenesis in the human host. The target should also be sufficiently different from any important host proteins to permit selectivity. It should be *druggable*; that is, a small molecule should be able to inhibit it. Enzymes make especially good targets for inhibition because they are usually at low concentrations inside cells, they are relatively well-understood mechanistically, they often interact with small-molecule substrates, and, as catalysts, their inhibition interrupts multiple reactions. Furthermore, pharmaceutical companies have a great deal of experience in developing enzyme inhibitors as drugs. It is therefore not surprising that most antiviral drug targets are virus-encoded enzymes. A second kind of target is a virus-encoded protein that can activate the drug to make it inhibitory to the virus (*lethal synthesis*), and that is sufficiently different from host counterparts to permit selectivity. An example is HSV thymidine kinase (TK), which activates ACV and its congeners.¹⁰⁸

Host proteins may also serve as antiviral drug targets, if they have an activity that is more important for viral replication than for host functions. A successful example of this approach is targeting the cell surface molecule, C-C chemokine receptor type 5 (CCR5), which led to the development of the anti-HIV drug maraviroc.^{207,297} Targeting of host functions is inherently more likely to result in toxicity than is targeting of viral functions. Conversely, it has been argued that viruses should be less likely to develop resistance against drugs that target host functions. Regardless, such mutants certainly can develop (e.g.,^{328,366}).

Factors Affecting the Development of Drug Resistance

If a drug acts selectively against a virus, the virus will generally be able to develop resistance to it. However, the frequency of drug-resistant mutants in a population, and how rapidly they arise depend on several factors: The first is the mutation rate of the virus. The higher the mutation rate, the more rapidly resistance can develop. Viral mutation rates are largely controlled by the fidelity of the polymerases that replicate the viral genomes. RNA viruses, which replicate using low-fidelity RNA polymerases, usually have the highest mutation rates, averaging one mutation per genome per replication cycle,^{87,232} whereas DNA viruses, whose DNA polymerases include proofreading 3' to 5' exonucleases that contribute to fidelity,¹⁷² have lower mutation rates. However, other factors, including nucleotide pools, which can be modulated by both viral and cellular factors, also contribute to mutation rate.

The second factor is the target size for mutation. The more sites where mutations can confer drug resistance, the more rapidly resistance can arise. For some drugs, such as ACV, many mutations can confer resistance, as any mutation that substantially reduces viral TK activity results in resistance. In addition, some sites within a gene are more or less likely to mutate than others. Homopolymeric runs in the HSV *tk* gene (e.g., a run of seven G's) are hot spots for frameshift mutations that confer ACV resistance.¹⁷⁰

The third factor is magnitude of replication of the virus. The more copies of viral genomes produced, the more opportunities

for resistance to arise. The fourth factor is the preexisting size of the virus population. The more virus present, even in the absence of drug selection, the more likely that drug-resistant mutants will be present among the array of genetic variants. Examples of these two factors that have an impact on HIV drug resistance are provided below in the section on drug resistance in antiviral therapy.

The fifth factor involves fitness (i.e., how well a genetic variant reproduces relative to other genetic variants, which can include “wild-type”). The more fit, the more likely resistance will occur. This is especially important for clinically significant drug resistance. For a virus to cause disease that is resistant to an antiviral drug, it must mutate not only to evade drug action, but also to retain pathogenicity. In vivo fitness and pathogenicity can be inferred from clinical studies, but can be assessed more directly in animal models. Although there is always the question of whether animal models are predictive of human disease, in most cases, there has been an excellent correlation between how drug-resistant mutants behave in clinical and animal studies. Some drug-resistant mutants, such as influenza viruses that are resistant to adamantanes, can be highly fit, both in cell culture and in animal models.^{15,355} Moreover, such mutants appear to be highly fit in human infections as well (reviewed in 144). Most ACV-resistant HSV mutants are highly fit in cell culture, but are much less so in animal models, which correlates with the low frequency that these mutants are recovered in immunocompetent humans (reviewed in 58 and 199). Still other drug-resistant mutants, such as certain HCMV mutants that are resistant to the drug foscarnet, can be less fit in cell culture, but not so impaired that they do not cause disease in patients.¹² Relative fitness is important both in the absence and in the presence of drug. If wild-type virus can replicate relatively well in the presence of drug (e.g., at subtherapeutic concentrations), then resistant mutants will be less likely to predominate. These various factors—mutation rate, target size, replication rate, pre-existing population, and fitness—can be taken into account in mathematical formulas and used to model the emergence of drug resistance (e.g.⁶¹).

In addition, these factors influence how different viral infections are treated. For example, HIV infections are now treated with combinations of antiviral drugs, whereas HSV infections are treated with single agents. This is discussed later in the sections on antiviral therapy.

MECHANISMS OF SPECIFIC ANTIVIRAL DRUGS

This section mainly considers agents that are currently approved for clinical use. No endorsement of the therapeutic value of these drugs is intended. For certain viruses that can be studied usefully in animal models, we discuss the effects of drug-resistant mutations on replication and pathogenesis in vivo.

Targeting Drugs to Specific Stages of Virus Infection

As detailed throughout this book, the infection of cells by viruses can be broken down into a common set of steps or stages, and most of these stages have been targeted by approved antiviral drugs (Fig. 13.1). The order of stages can differ for different viruses, and some viruses have stages that are not

FIGURE 13.1. Antiviral drugs block various stages of viral replication. A generic replication cycle of viruses in cells is cartooned, showing the stages of infection, which different drug classes block. These include attachment and entry, uncoating, gene expression, genome replication, assembly and maturation, and egress and release. Examples of specific drug classes are provided. For some viruses (e.g., human immunodeficiency virus [HIV]), the order of the stages differs from that in this cartoon (see Fig. 13.2). Some viruses lack stages shown here (e.g., release), whereas other viruses have additional stages. (Modified from Yeh RW, Coen DM. Pharmacology of viral infections. In: Golan DE, Tashjian AH, Jr., Armstrong EJ, et al., eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. Third edition. Philadelphia: Lippincott Williams & Wilkins, 2012:649–673.)
